(Received 24 September 2008; published 17 December 2008)

We investigate the time taken for global collapse by a dipolar Bose-Einstein condensate. Two semi-analytical approaches and exact numerical integration of the mean-field dynamics are considered. The semi-analytical approaches are based on a Gaussian ansatz and a Thomas-Fermi solution for the shape of the condensate. The regimes of validity for these two approaches are determined, and their predictions for the collapse time revealed and compared with numerical simulations. The dipolar interactions introduce anisotropy into the collapse dynamics and predominantly lead to collapse in the plane perpendicular to the axis of polarization.

Long coherence times and a high degree of controllability make ultracold atomic gases suited to the study of nonequilibrium states of many-particle quantum systems. One example is the collapse of a Bose-Einstein condensate (BEC) [1–8] by using a Feshbach resonance to change the s-wave scattering length \( a_s \) from positive to negative. Two limiting cases can be identified: local and global collapse, respectively, upon whether the (imaginary) healing length \( \lambda \) or the size of the BEC. The mechanism of collapse is an instability of the monopole collective excitation mode \( \omega_k \), which is the time taken for atomic three-body losses to become significant [5]. Mean-field simulations including three-body loss have reproduced experimental results reasonably well [14].

The \(^{52}\)Cr condensates made by Griesmayer et al. in Stuttgart [15] are the first to have large dipole-dipole interactions (in addition to the s-wave). Dipolar interactions are long range and partially attractive, and thus the properties of dipolar BECs (DBECs) are rather intriguing. In recent experiments [16,17] the collapse of a DBEC was triggered by reducing the repulsive s-wave interactions, with the collapse occurring anisotropically and on a global scale. Motivated by these experiments, we theoretically model the time scale for the global collapse of a DBEC. This is achieved through mean-field simulations and two semi-analytical methods. The first semi-analytical method is based on a plasma physics treatment of the collapse of electrostatic [18,19] and electromagnetic [20,21] wave packets. We apply it to the case where the initial state is weakly interacting. The second method is valid in the opposing interaction-dominated Thomas-Fermi (TF) regime; essentially we run the usual ballistic expansion equations [22,23] in reverse.

The macroscopic wave function describing a BEC, \( \phi(r,t) \), satisfies the Gross-Pitaevskii equation (GPE)

\[
\frac{i\hbar}{\hbar} \frac{\partial \phi}{\partial t} = \left( -\frac{\hbar^2 \nabla^2}{2m} + V(r) + g |\phi|^2 + \Phi_{dd} - i\frac{\hbar K_3}{2} |\phi|^4 \right) \phi, \tag{1}
\]

where \( g = 4\pi \hbar^2 a_s / m \) and \( m \) is the atomic mass. The confining harmonic potential \( V(r) = m \omega_0^2 (r^2 + y^2) / 2 \), where \( r^2 = x^2 + y^2 \), is cylindrically symmetric, with radial (axial) frequency \( \omega_0 \) (\( \omega_\perp = \gamma \omega_0 \)). The term \( \Phi_{dd}(r,t) = \int d^3r \int d^3r' U_{dd}(r-r') \eta(t) \) accounts for the dipolar interactions \( U_{dd}(r) = \mu_0 \mu^2 / \left( -3 \cos^2 \theta / (4\pi r^3) \right) \), where \( \theta \) is the angle between the separation vector \( r-r' \) and the polarization direction, taken to be the \( z \) direction. The strength of the dipolar interactions is characterized in terms of \( k_0 = \gamma a_d / a_r \), where \( a_d = \mu_0 \mu^2 m / (12\pi \hbar^2) \) is the length scale of the dipolar interactions. The last term in the GPE represents three-body loss where \( K_3 \) is the recombination rate. For the semi-analytical methods we assume that the DBEC collapses globally, maintaining a single-peaked density profile. In the GPE simulations some features of local collapse, discussed elsewhere [24], are observed. This typically occurs after considerable global collapse and as such the dynamics remain in good agreement with global collapse predictions.

Analogous collapse occurs in plasma physics where electrostatic [18,19] and electromagnetic [20,21] wave packets in a turbulent plasma undergo nonlinear self-focusing and Zakharov collapse. Following approaches for plasma wave packet dynamics [19] and work by Lushnikov for DBECs [25], the equation of motion for the mean square radius of the DBEC, \( \langle r^2 \rangle = (r^2 + z^2) \), is

\[
\frac{\partial^2 \langle r^2 \rangle}{\partial t^2} = \left( \frac{6E_0}{mN} - \frac{2E_k}{mN} - 5\omega_0^2 \langle r^2 \rangle - 5\omega_0^2 \langle z^2 \rangle - 1 \langle z^2 \rangle \right), \tag{2}
\]

where \( \langle r^2 \rangle = \int d^3r |\phi|^2 d^3r \) and \( \langle z^2 \rangle = \int d^3z |\phi|^2 d^3z \). We assume an initial stable state with total and kinetic energy \( E_0 \) and \( E_{K0} \) and

\[
\langle r^2 \rangle = \langle r^2 \rangle_0, \quad \langle z^2 \rangle = \langle z^2 \rangle_0 \quad \text{with} \quad d \langle r^2 \rangle_0 / dt = d \langle z^2 \rangle_0 / dt = 0.
\]
FIG. 1. (Color online) Regimes of validity for the GA and TF ground states in the parameter space of \( k_s \) and \( k_d \). Above the short-dashed black curve there are no stable ground states to the GPE. The red solid (green long-dashed) curve bounds the regions of validity of the GA (TF) solution, defined to be when their energy is within 5% of that of the true GPE ground state. Considered are the trap ratios \( \gamma^2 = \) (a) 0.1, (b) 1, and (c) 10. In each of the figures the circles are the values for \( k_s \) and \( k_d \) that are employed in Figs. 2(a)–2(c) and 3(a)–3(c) [Figs. 3(d)–3(f)].

Upon changing the strength of the s-wave interactions from \( a_{i0} \) to \( a_s \), the upper bound for the final value of \( \langle \rho^2 \rangle \) is

\[
\langle \rho^2 \rangle_y = \langle \rho^2 \rangle_0 + \frac{1}{mN} [6E - 2E_{K0} - 5m\omega_0^2 N(\gamma^2 - 1)(\zeta^2_0)]^2, \tag{3}
\]

where \( E' = E_0 - E_{G0}(1 - a_s/a_{i0}) \). Rearranging, the upper bound for the collapse time is

\[
t_c \leq \left| \frac{\langle \rho^2 \rangle_y - \langle \rho^2 \rangle_0}{6E' + mN - 2E_{K0}/mN - 5m\omega_0^2 (\gamma^2 - 1)(\zeta^2_0)} \right|^{1/2}, \tag{4}
\]

where collapse occurs when \( \langle \rho^2 \rangle_y = 0 \).

In the limit of weak interactions the condensate can be modeled by a Gaussian ansatz (GA):

\[
\psi_{\text{GA}} = \sqrt{N} / p_z \pi^{1/4} \exp \left( -\frac{\rho^2}{2\rho^2} - \frac{z^2}{2l^2} \right). \tag{5}
\]

The energy \( E \) of this ansatz is evaluated using the GPE energy functional, and has four contributions: kinetic (\( E_k \)), trap (\( E_T \)), s-wave (\( E_3 \)), and dipole (\( E_d \)) [26]. By minimizing \( E \) with respect to the radii \( \rho \) and \( l_z \) [26,27], the variational solutions for \( E_0, \langle \rho^2 \rangle, \) and \( \langle \rho^2 \rangle \) are found. This enables the time it takes for the BEC to go from \( \langle \rho^2 \rangle_0 \) to \( \langle \rho^2 \rangle \) to be evaluated, via Eq. (4). For \( \langle \rho^2 \rangle = 0 \), this defines the collapse time.

When the interactions become dominant it is then appropriate to use the TF approximation, wherein the zero-point kinetic energy is neglected. In this limit, the nondipolar GPE under harmonic trapping is known to support an exact scaling solution given by [22,23]

\[
n(r,t) = n_0(t) \left( 1 - \frac{\rho^2}{R_p^2(t)} - \frac{z^2}{R_z^2(t)} \right), \tag{6}
\]

\[
v(r,t) = \frac{1}{2} \nabla \left[ \alpha_p(t) \rho^2 + \alpha_z(t) z^2 \right], \tag{7}
\]

where \( n_0(t) = 15N/[8\pi R_p^2(t) R_z(t)] \). This class of solution remains exact even in the presence of dipolar interactions [28,29]. Substitution into the GPE yields the equations of motion (8) and (9) for the radii [29]. These describe the two lowest-lying excitation modes, namely, the axis-symmetric quadrupole and the monopole excitations.

It is important to establish how well the TF and GA approximations reproduce the exact ground state in the parameter space of \( k_s \) and \( k_d \). We define their regimes of validity to be when the energy of the GA or TF solution differs by less than 5% from the energy of the GPE solution. Figure 1 maps out these regimes for \( \gamma^2 = \) (a) 0.1, (b) 1, and (c) 10. The short-dashed black curve marks the threshold for collapse: above it there are no stable ground-state solutions to the GPE. Hence, for a given \( k_s \) there is a unique \( k_d \) below which the system is unstable to collapse. The region bounded by the solid red (long-dashed green) curve marks the region of validity for the GA (TF) solution. In general we find that the GA gives a good approximation to the ground state for weak interactions and in regions close to the collapse threshold. By contrast,
the TF solutions are most accurate in the presence of strong s-wave interactions and for parameters well away from the collapse threshold. Furthermore, trap geometry plays a key role in the validity of the solutions. In prolate, $\gamma<1$, traps the GA (TF) approximation has a large (small) region in which it is valid, while for oblate, $\gamma>1$, traps the opposite is true. This is because a prolate (oblate) dipolar BEC experiences a net attractive (repulsive) interaction due to the dominance of end-to-end (side-by-side) dipoles, and for such interactions the GA (TF) approximation works well. Note that close to the collapse threshold zero-point kinetic energy plays a significant role in stabilizing the condensate and so the TF approximation does not provide a good description for ground states there. However, the TF approach can still be employed to model the collapse dynamics providing that the interactions dominate over zero-point kinetic energy during the dynamics. In practice this is achieved by beginning with an initial state that is well within the regime of stability (a TF initial state), and then suddenly switching to a point in the parameter space that is deep in the collapse regime, i.e., bypassing the threshold for collapse. As the density increases during collapse $E_S+E_D$ continues to dominate $E_K$.

We now study the dynamical collapse in the TF limit. We define the scaling parameters $\lambda_\rho(t)=R_\rho(t)/R_{\rho0}$, where $R_{\rho0}$ are the initial radii ($i=\rho,z$). Then, under general time-dependent changes in $k_\rho(t)$ and $k_z(t)$, the time evolution of $\lambda_\rho(t)$ and $\lambda_z(t)$ is given by

$$\dot{\lambda}_\rho = -\lambda_\rho + \frac{\alpha}{\lambda_\rho \lambda_z} \left[ \frac{k_\rho(t)}{\lambda_\rho^2} - k_d(t) \left( \frac{1}{\lambda_\rho^2} + \frac{3\kappa^2 f(\kappa_0 \lambda_\rho/\lambda_z)}{2(\kappa_0^2 \lambda_\rho^2 - \lambda_z^2)} \right) \right],$$

$$\dot{\lambda}_z = -\gamma^2 \lambda_z + \frac{\alpha \kappa \lambda_\rho}{\lambda_z^2} \left[ \frac{k_z(t)}{\lambda_z^2} + k_d(t) \left( \frac{2}{\lambda_z^2} + \frac{3f(\kappa_0 \lambda_\rho/\lambda_z)}{\kappa_0^2 \lambda_\rho^2 - \lambda_z^2} \right) \right],$$

where the unit of time is $1/\omega_\rho$, $\alpha=15\kappa_0^2 R_{\rho0}^2/\rho_0$, and $f(\kappa) = 1 + 2\kappa^2 (1 - \kappa^2)^{-3/2}$. The initial aspect ratio $\kappa_0$ is evaluated from Eqs. (8) and (9) for $\lambda_\rho=0$.

Figure 2 shows the evolution of $\lambda_\rho$ (solid curves) and $\lambda_z$ (dashed curves) as calculated from the TF equations (thick black curves) and numerical simulation of the GPE with (thin red) and without (medium green) three-body loss. Specifically, the case where $k_\rho$ is switched from $k_{\rho0}=60$ to 0 ($k_d=k_{\rho0}=30$) is considered, for $\gamma^2=(a) 0.1$, (b) 1, and (c) 10. For these parameters the initial state of the BEC spans the regimes of validity of the TF and GA approaches. On comparing the GPE results to the TF analysis, excellent agreement for the majority of the collapse is observed. Significant deviations occur only close to the point of collapse ($\lambda_\rho \rightarrow 0$) when the GPE collapse bounces and turns into an expansion of the system, consistent with the recent observation of a $d$-wave explosion following collapse [17]. Importantly, the collapse is highly anisotropic and occurs primarily in $R_\rho$, i.e., $R_\rho/R_z \rightarrow 0$ as $t \rightarrow t_c$, consistent with recent experimental observations [17]. The same behavior occurs in lower-hybrid collapse in turbulent plasmas [19,30]. In the case of s-wave scattering, both $R_\rho$ and $R_z$ collapse at the same rate, with $R_\rho \approx (1-t/t_c)^{1/2}$, analogous to electrostatic Zakharov collapse [19]. Furthermore, the fact that the TF parabolic scaling solutions give such a good description of the collapse indicates that, for the parameters considered, collapse is primarily a global effect and proceeds through a quadrupole collective mode. From the GPE simulations a collapse time is defined in terms of a sudden onset of loss (red triangle) [31] for $K_3 >0$. Numerical simulations indicate that in the limit $K_3 \rightarrow 0$ this coincides with the time at which $\lambda_\rho=0$ (green circle).

Hence, our results indicate that GPE simulations without three-body losses can be used to infer an upper limit for the collapse time. For pancake-shaped geometries ($\gamma \gg 1$), the
TF and GPE solutions exhibit significant oscillations in $\lambda_z$ before collapse, as seen in Fig. 2(c).

From Eq. (4), using the GA, an upper bound for the collapse can be calculated (black squares in Fig. 2). For $\gamma = 0.1$, the upper bound is consistent with GPE results. As we move away from the regime where the GA is valid [Figs. 2(b) and 2(c)], the upper bound for the collapse time becomes inconsistent with the GPE results.

Figure 3 presents the collapse times as $k_z$ is switched from $k_{x0}$ to $k_x$, for various geometries, as evaluated via Eq. (4) (solid black), Eqs. (8) and (9) (black circles), and GPE simulations (red squares) and without (green +) three-body losses. For $k_x < k_{x0}^*$ (left of the vertical dashed lines), the final state solutions are collapsed states, with the time it takes to collapse increasing as $k_x$ approaches $k_{x0}^*$ from below. In all of the regimes presented we find that the TF approximation provides a good estimate for the upper bound of the collapse time. In contrast, Eq. (4) is consistent with the GPE simulations only in the limit of very weak interactions. Note the appearance of a sudden step in the TF and GPE collapse times in Fig. 3(f). When the dipolar interactions dominate, the collapse is highly anisotropic and complete collapse occurs first in $R_x$. However, for large and attractive s-wave interactions, the collapse can become almost isotropic and for pancake-shaped systems complete collapse can occur first in $R_z$. This step represents the transition between a complete collapse in $R_z$ (left of the step) and $R_y$ (right of the step).

In summary we have presented two simplified models of the collapse time of a DBEC, and compared them with exact numerical integration of the dipolar GPE. When the atomic interactions are weak or attractive, a GA for the initial DBEC can be assumed with an upper bound for the collapse time derived through a highly simplified equation of motion for the radius [Eq. (4)]. In the opposing regime, where interactions dominate, TF equations of motion for the radii provide a convenient and approachable method to derive the time for global collapse. The validity of these two regimes is determined by the strength of the interactions and the aspect ratio of the trap. When dipolar interactions dominate, the collapse occurs in the plane perpendicular to the axis of polarization. The excellent agreement, for the parameters considered, between the TF dynamics and the full numerical simulations indicates that the collapse primarily occurs in a global manner and proceeds through a quadrupolar collective motion, consistent with the recent experimental observations [16, 17]. Finally, for oblate geometries, we observe two prominent deviations from this general behavior. First, significant oscillations in $\lambda_z$ can occur during collapse and, second, for strong attractive s-wave interactions the collapse predominantly occurs in $z$ rather than $\rho$.

This work was funded by the ARC (C.T., A.M., A.M.M.), the Canadian Government, (N.G.P.), EPSRC and the Royal Society (S.L.C.) and NSERC (D.H.J.O.D.).

[31] A sudden onset of loss is evaluated via $\dot{\rho}/\rho^2$ which spikes at the onset of loss. For systems with significant loss this agrees well with the analysis presented in Ref. [5], with the advantage that in the limit $K_3 \rightarrow 0$ the onset of loss can still be evaluated.
