Summary

Despite progression in anticancer drug development and improvements in the clinical utilisation of therapies, current treatment regimes are still dependent upon the use of systemic antiproliferative cytotoxic agents. Although these agents are unquestionably potent, their efficacy is limited by toxicity toward ‘normal’ cells and a lack of tumour selective targeting, resulting in a therapeutic index which is modest at best. Consequently, the development of more tumour selective cancer treatments, with better discrimination between tumour and normal cells is unequivocally an important goal for cancer drug discovery. One such strategy is to exploit the tumour phenotype as a mechanism for tumour-selective delivery of potent therapeutics. An exciting approach in this area is to develop anticancer therapeutics as prodrugs, which are non-toxic until activated by enzymes localised specifically in the tumour. Enzymes suitable for tumour-activated prodrug development must have increased activity in the tumour relative to non-diseased tissue and an ability to activate the prodrug to its active form. One class of enzyme satisfying these criteria are the tumour endoproteases, particularly the serine- and metallo- proteases. These proteolytic enzymes are essential for tumour angiogenesis, invasion and metastasis, the major defining features of malignancy. This review describes the concept behind development of tumour-endoprotease activated prodrugs and discusses the various studies to date that have demonstrated the huge potential of this approach for improvement of cancer therapy.

Keywords: Cancer therapy, Endoprotease, Prodrug, Drug delivery, Matrix metalloproteinase (MMP), Prostate specific antigen (PSA), Cancer pharmacology.
**Abbreviations:**

ECM, extracellular matrix; EGFR, epidermal growth factor receptor; FITC, fluorescein isothiocyanate; L-Dox, leucine-doxorubicin; MMP, matrix metalloproteinase; MTD, maximum tolerated dose; MT-MMP, membrane-tethered matrix metalloproteinase; NQO1, NAD(P)H: quinone oxidoreductase type 1; PSA, prostate specific antigen; TAP, tumour activated prodrug; TNFa, tumour necrosis factor alpha.
Introduction

Despite vast improvements in detection, diagnosis and treatment over the past decade, cancer still remains one of the most frequent causes of death worldwide (Varmus, 2006). Therefore, new more effective treatment strategies are required to impact upon this issue. To date, surgical resection remains the number one priority for treatment of solid tumours. Despite this, for the majority of solid tumours cure by surgical resection is not feasible, either as a consequence of tumour accessibility, tumour pathology or the presence of tumour spread and metastasis. Therefore, chemotherapeutic interventions are required and essential both as a treatment in their own right and as an adjuvant to localised treatment such as surgery and radiotherapy. Whilst many advances have been made in the area of anticancer drug development (reviewed in Collins et al., 2006; Newell, 2005), “classical” antiproliferative cytotoxic agents still form the basis of many current treatment regimens (Collins et al., 2006). Despite being potent with the ability to kill large numbers of tumour cells, the clinical efficacy of these “classical” agents is limited by their unavoidable toxicity to ‘normal’ cells and their lack of tumour selective targeting. With such compounds, the therapeutic index for tumour versus normal tissue is modest, toxic side effects are the norm and the development of resistance often occurs. As such, most currently utilised anticancer agents have a very small therapeutic index based on the high frequency of systemic toxicities and the need for large concentrations of active drug at the tumour site (Verweij et al., 2000). Consequently, a plateau of effectiveness has been reached with these agents.

An increased understanding of the molecular basis of cancer has led to many advancements in cancer chemotherapy which has now entered an era of “targeted molecular therapeutics”- agents exploiting defined abnormalities responsible for the
causation, maintenance, expansion or metastatic potential of cancer (reviewed in (Collins et al., 2006; Newell, 2005). The development of new therapeutics with increased tumour selectivity, better discrimination between tumour and normal tissue, lower systemic toxicity and thus a larger therapeutic index, is possibly the most important aim of current cancer drug discovery. One such strategy is the development of agents to perturb the dysregulated molecular pathways involved in cancer development and progression, e.g. Gleevec (imatinib) and Zolinza (vorinostat), resulting in therapies directed at the precise molecular pathology driving progression of specific tumour types (reviewed in (Collins et al., 2006; Newell, 2005). Despite these successes, the identification of such critical targets for drug development is complicated due to both the characteristic genetic instability of cancer and the diverse nature of genetic changes involved in the tumorigenic process (Collins et al., 2006; Huang et al., 2001).

An alternative strategy for more effective and targeted cancer therapeutics is the development of agents which take advantage of the tumour phenotype rather than intracellular signalling pathways, i.e. differential cell-matrix interactions, altered cell surface receptor expression and increased capacity for proteolytic degradation (Huang et al., 2001). In this respect, epidermal growth factor receptor (EGFR) has been demonstrated as a clinically viable drug target as evidenced by the success of the small molecule drugs Iressa (gefitinib) and Tarceva (erlotinib) (Collins et al., 2006).

A further strategy to increase drug targeting and decrease systemic toxicities is to deliver potent chemotherapeutics selectively to their intended site i.e. the tumour microenvironment. One such approach is the development of therapeutic agents as non-toxic prodrugs, termed tumour-activated prodrugs (TAPs), in a form whereby the potent therapeutic entity is masked until being activated by exploitation of unique
phenotypic differences present in the tumour environment, (depicted in Figure 1) (Denny, 2001).

Classically, the term prodrug encompasses all compounds that are activated after administration either enzymatically, chemically or spontaneously to form a pharmacologically active species. In this sense the concept of prodrugs within cancer chemotherapy is not new as demonstrated by cyclophosphamide, a clinically utilised prodrug of a nitrogen mustard alkylating agent activated in the liver by the cytochrome P450 enzyme system (Boddy et al., 2000; Connors, 1986; Torkelson et al., 1974). In the context of cyclophosphamide and the majority of cancer chemotherapeutics classified as prodrugs to date, these agents are not designed as TAPs, but rather as derivatives to modify drug uptake or pharmacokinetics. Unlike the TAP strategy, the use of prodrugs such as these is still limited by normal tissue toxicities due to their potential activation outside of the tumour environment (Rooseboom et al., 2004). As such, this family of prodrugs can be regarded as those in which the pharmacological properties of the active drug are modified to facilitate increased tumour delivery rather than those which are directed specifically at the tumour (Bruno et al., 2007; Ganesh, 2007; Rooseboom et al., 2004).

With the rapid expansion in our understanding of the molecular pathology of cancer and improved knowledge of “classical” and more recently “targeted” cancer therapies, we now have a robust framework by which to progress the development and assessment of therapeutics directed to the tumour for selective conversion to active therapeutic agents, specifically tumour activated prodrugs (TAPs).

**Tumour Activated Prodrugs (TAPs).**
As mentioned above, Tumour activated prodrugs (TAPs) are systemic compounds that are activated selectively in tumour tissue by exploiting a unique physiological, metabolic or genetic difference between tumour and normal cells (Denny, 2001). TAPs must undergo selective cellular metabolism in tumours to generate their potent therapeutic agent. In general, TAPs are comprised of a minimum of three domains: trigger, linker and effector, where the “trigger” (controlling selectivity) is joined to the “effector” (responsible for therapeutic effect) by a “linker”; the prodrug remaining non-toxic until activation of the trigger (shown in figure 1) (Denny, 2001).

The primary step in the development of TAPs is the identification of enzymes capable of metabolising these agents selectively within tumour tissue. There is considerable evidence demonstrating differential expression of a panoply of enzymes between normal and tumour tissue, although consistent patterns of enzyme upregulation so far remain elusive (Denny, 2001). The ideal characteristics for tumour enzymes suitable for targeting by TAPs are;

i) Good characterisation of the enzyme or family of enzymes possessing a known role in tumour development and/or progression

ii) Demonstration of a high affinity of the enzyme for the prodrug

iii) Significantly elevated expression in the disease state and activity in the tumour environment

iv) Low or negative expression and lack of enzymatic activity in non-diseased tissue

v) No presence of the enzyme in a prodrug-activating form in patient serum

vi) Capability by the enzyme for selective and rapid activation of the prodrug
In the context of TAPs, several phenotypic characteristics of the tumour have been suggested as selective prodrug targets involving a range of endogenous enzyme classes including oxidoreductases, transferases, hydrolases, and lyases (reviewed in Rooseboom et al., 2004). An example of one area which has attracted considerable attention as a target for TAP therapeutics is tumour hypoxia, induced as a consequence of the poorly defined vascular network of many solid tumours. Bioreductively activated prodrugs e.g. Tirapazamine and banoxantrone (AQ4N) (McKeown et al., 2007; Patterson et al., 2000), specifically target hypoxic cells by becoming selectively activated under low oxygen tension by enzymes including NQ01 and cytochrome P450 reductase (McKeown et al., 2007). This class of TAP is showing great promise in cancer clinical trials (McKeown et al., 2007). Targeting enzymes centrally involved in the main defining features of cancer is an attractive strategy for TAP development since these will provide optimal targets for TAPs by virtue of the phenotypic differences between “normal” and tumour cells. One class of enzyme which satisfy all criteria for TAP development and have been heavily implicated in tumour development and progression are the proteolytic endoproteases, the main focus of this review.

**Central involvement of endoproteases in cancer development**

The major defining features of malignant tumours are their ability to acquire an improved vasculature system, penetrate into surrounding normal tissues and disseminate to distant sites. Each one of these processes relies heavily upon the increased expression and activity of diverse extracellular endoproteases from multiple enzymatic classes, namely the metalloproteases and the serine, threonine, cysteine and aspartic proteases. These proteases constitute the cancer degradome- the repertoire of
proteases that cells and tissues co-ordinately regulate in order to modulate their local environment (Lopez-Otin et al., 2002; Overall et al., 2007). These endoproteases are frequently upregulated within tumour tissue where they promote the development and expansion of the tumour, formation of new blood vessels to support the burgeoning energy demands of the rapidly growing tumour, and facilitate the metastasis of cancer cells to distant organs (Egeblad et al., 2002).

It has long been recognised that cellular invasion of basement membranes and connective tissue stroma and angiogenesis and metastasis, involve the actions of diverse extracellular proteases, particularly the matrix metalloproteinase (MMP) and serine protease families. The initial belief that these proteases function solely to mediate tissue destruction and clear an invasive path allowing cell migration and thus tumour expansion is now known to be oversimplistic, with these enzymes having major roles in growth factor activation, cellular adhesion, cellular survival and immune surveillance to name but a few (Egeblad et al., 2002; Hojilla et al., 2003; McCawley et al., 2001). There is now a considerable body of literature demonstrating elevated expression of many of these endoproteases in primary tumours and metastases, with the majority demonstrating an association to tumour progression or validity as prognostic indicators of clinical outcome (Brinckerhoff et al., 2000; Kamat et al., 2006; Vizoso et al., 2007). Taken together their broad but essential role in tumorigenesis and their relationship to disease prognosis, these enzymes can be defined as a significant force in the phenotypic evolution of cancer.

**Tumour Endoproteases as targets for tumour selective anticancer drug delivery**

The involvement of endoproteases in tumour development, expansion and metastasis is unequivocal, as outlined above and reviewed extensively elsewhere (Borgono et al.,
In terms of drug development, proteases provide a significant opportunity as they account for approximately 2% of mammalian genes and represent 5% of all drug targets (Lee et al., 2004; Overall et al., 2007; Overall et al., 2006b). Within the protease family the serine and metalloproteases constitute the largest group (accounting for 65% of all proteases) with central roles in neoplastic and malignant processes (Borgono et al., 2004; Deryugina et al., 2006; Lopez-Otin et al., 2002; Mohamed et al., 2006; Overall et al., 2007). The main driving principles behind utilisation of an enzyme for TAP development is increased activity in the tumour environment relative to non-diseased tissue, and an ability to selectively cleave the prodrug to its active form (Denny, 2001). In this respect, the serine and metalloproteases are ideal candidates for TAP development due to both their elevated activity in the extracellular tumour environment and their ability to selectively and specifically cleave short peptide sequences. Consequently, the increased endoprotease activity within tumours relative to non-diseased tissue can be harnessed to activate peptide-conjugated prodrugs of potent anticancer therapeutics, resulting in high levels of the active agent at the tumour and low or negative drug levels in ‘normal’ tissues. The concentration of active therapeutic selectively released and deposited in the tumour is highly dependent upon both the catalytic efficiency of the targeted endoprotease and the level to which the enzyme is expressed within the tumour. As such, when developing such strategies, careful consideration must be given to target efficiency and suitability for TAP activation, as well as the potency and mechanism of action for the active therapeutic agent. In recent years several endoprotease targeted TAPs have been reported in the literature, initially against the serine protease Prostate
Specific Antigen (PSA), and latterly the matrix metalloprotease (MMPs) family, as discussed below.

**Serine Proteases: Prostate Specific Antigen (PSA) as a target for Prodrugs:** The serine protease Prostate Specific Antigen (PSA), is a secreted member of the kallikrein gene family, which as the name implies is expressed selectively in prostatic tissue (Borgono et al., 2004). In cancers of the prostate, PSA levels are significantly elevated relative to non-diseased tissue (Denmeade et al., 2001; Wong et al., 2001). In addition, PSA is a clinically utilised serological diagnostic marker of prostate cancer, with higher levels being indicative of a larger tumour burden or metastatic disease (Rao et al., 2007; Reynolds et al., 2007). In terms of PSA as a target for TAP development via the criteria outlined above; PSA is elevated and proteolytically active at high levels in prostatic tumours whilst all normal tissues lack detectable PSA activity, and it is capable of selective and rapid activation of peptide-conjugated prodrugs (DeFeo-Jones et al., 2000; Denmeade et al., 1998; Reynolds et al., 2007; Wong et al., 2001). Furthermore, PSA present in patient serum is proteolytically inactive and incapable of prodrug activation due to formation of a complex with the plasma protease inhibitors α1-antichymotrypsin and α2-microglobulin, thereby fulfilling another major criteria for TAP development (Otto et al., 1998; Reynolds et al., 2007). Taken together, these characteristics of PSA strongly supported its potential for TAP development, as discussed below.

**Matrix Metalloproteinases (MMPs) as targets for Tumour Activated Prodrugs:** The Matrix Metalloproteinases (MMPs), a family of at least 24 zinc dependent endoproteases, possess the ability to degrade most, if not all components of the
extracellular matrix (ECM) and basement membrane, contributing to the formation of a microenvironment permissive of tumour growth, angiogenesis and metastasis (Deryugina et al., 2006; Egeblad et al., 2002). A number of MMPs have been associated with tumour cell invasion evidenced by a significant correlation between the extent of local tissue penetration and MMP levels (Deryugina et al., 2006; McCawley et al., 2000; McCawley et al., 2001).

In addition to the classical role of MMPs in the degradation of the ECM, MMPs are also able to cleave a wide range of non-matrix substrates including those involved in apoptosis, cell dissociation, cell-cell communication and cell division, thereby negating the initial view that MMPs functioned purely to “bulldoze” the ECM and facilitate cell invasion (Deryugina et al., 2006; Egeblad et al., 2002; Hojilla et al., 2003; McCawley et al., 2001). Extensive studies have demonstrated frequent overexpression of several MMPs in many forms of human tumour (Atkinson et al., 2007b; Brinckerhoff et al., 2000; Hoekstra et al., 2001; Kamat et al., 2006; Vizoso et al., 2007) with a clear relationship between increased MMP expression and poor clinical outcome in a number of cancers including; breast (MMP-11), colon (MMP-1), gastric (MMP-2 and MMP-9), non-small cell lung cancer (MMP-13), oesophageal (MMP-7), small cell lung cancer (MMP-3, MMP-11 and MMP-14) (Hoekstra et al., 2001; Vizoso et al., 2007). Furthermore, expression of specific MMPs has been shown in many independent studies to serve as both prognostic indicators of clinical outcome and markers of tumour progression in a diverse range of tumour types (Brinckerhoff et al., 2000; Kamat et al., 2006; Vihinen et al., 2002; Vizoso et al., 2007; Zucker et al., 2004).

The MMPs may be divided into eight distinct groups: five are secreted and three are membrane bound (MT-MMPs) (Egeblad et al., 2002). The majority of
MMPs, with the exception of the MT-MMPs and MMP-11, -21, -23 and -28, are secreted by the cell as inactive zymogens and require activation extracellularly by cleavage of the N-terminal pro-domain resulting in a fully functional enzyme (Brinckerhoff et al., 2002). In contrast, the MT-MMP family are not secreted from the cell but are activated intracellularly and presented on the cell surface in a proteolytically active state (Brinckerhoff et al., 2002; Osenkowski et al., 2004). Therefore, all MMPs possess proteolytic activity in the extracellular microenvironment within the tumour, distinct from the lack of activity present in ‘normal’ tissues.

Many eloquent experiments have been performed in recent years which undeniably demonstrate a crucial role for MMPs in tumorigenesis through a number of potential mechanisms, detailed extensively in the literature (Deryugina et al., 2006; Egeblad et al., 2002; Hojilla et al., 2003; McCawley et al., 2000; McCawley et al., 2001). For example, overexpression of MMP-14 (MT1-MMP) in cell lines null for MMP-14 or non-malignant epithelial cells afforded the cells the capability to invade (Soulie et al., 2005). Conversely, in many models in which MMP-14 is knocked down, a reduction in cellular invasiveness and tumour progression is observed (Deryugina et al., 2006; Rutkauskaite et al., 2005; Sabeh et al., 2004; Ueda et al., 2003; Zhang et al., 2006). Therefore, the MMPs are a family of extracellular proteases which demonstrate the potential to become efficient drug targets for TAP development, facilitating release of therapeutic agents selectively in the tumour microenvironment.

An interesting point when considering the value of MMPs for TAP development is the actual sub-tumoral expression of the specific protease. In many cases, MMPs within the tumour are not-specifically produced by the tumour cells
themselves, but rather by the host stromal cells within or adjacent to the invading tumour (Egeblad et al., 2002; Jodele et al., 2006). Although initially thought to be problematic for TAP development, in reality this may actually prove to be beneficial for this strategy for two reasons. Firstly, the important issue for TAP success is the elevation of active MMP selectively within the tumour microenvironment, leading to local release of the active therapeutic and toxicity toward tumour cells. Since MMP activity is known to be restricted to the tumour mass, the expression of MMPs by stromal cells only increases the level of target for tumour-selective TAP activation. Secondly, stromal cells producing MMPs are known to facilitate malignant behaviour (Egeblad et al., 2002; Jodele et al., 2006), therefore toxicity against these cells may in itself prove beneficial. As such, the expression of MMPs by many cell types within the tumour microenvironment is perceived a positive factor for development and success of tumour-selective MMP-activated TAPs.

Tumour activated prodrugs directed to the serine protease, Prostate Specific Antigen (PSA)

There are now numerous examples in the literature regarding the targeting of PSA with a variety of TAPs. Drug conjugates including doxorubicin (DeFeo-Jones et al., 2002; Denmeade et al., 1998; DiPaola et al., 2002; Wong et al., 2001), vinblastine (DeFeo-Jones et al., 2002), 5-fluorodeoxyuridine (Mhaka et al., 2002), thapsigargin (Denmeade et al., 2003) and paclitaxel (Kumar et al., 2007) have been investigated and resulted in promising preclinical data. The creation of a proteolytic cleavage map of PSA against its physiological substrate semenogelin I, led to the identification of a heptapeptide sequence rapidly hydrolysed by PSA (DeFeo-Jones et al., 2000). Covalent linkage of this peptide sequence to the aminoglycoside portion of
doxorubicin (a topoisomerase II poison) led to the creation of L-377202, a TAP hydrolysed by PSA resulting in the release of leucine-doxorubicin and subsequently doxorubicin (DeFeo-Jones et al., 2000). When evaluated in preclinical studies, a substantial therapeutic index was demonstrated for L-377202 and molar equivalent doses of the prodrug eight to nine-fold higher than doxorubicin alone could be administered *in vivo* without additional toxicity (DeFeo-Jones et al., 2000; DiPaola et al., 2002). In clinical trials, only a 1.3-fold molar increase in prodrug relative to doxorubicin alone was administered due to dose limiting neutropenia, although at this dose a substantial reduction was noted in mean PSA percentage, an indicator of tumour volume (DiPaola et al., 2002). Further clinical trials are yet to be reported for this agent.

Following demonstration of proof of concept with L-377202, several other PSA directed chemotherapeutic TAPs have been now reported with relative success (DeFeo-Jones et al., 2002; Denmeade et al., 2003; Kumar et al., 2007; Mhaka et al., 2002). Using the chemical strategy outlined for L-377202, DeFeo-Jones and coworkers subsequently developed a PSA-directed TAP incorporating the microtubule-targeted agent vinblastine (depicted in figure 2), with the aim of increasing efficacy over L-377202 against advanced prostate cancer (DeFeo-Jones et al., 2002). In preclinical studies, this TAP demonstrated PSA-dependent activation, significantly lower toxicity in both mice and dogs compared to desacetyl-vinblastine (effector) alone, and a significant inhibition in the growth of PSA-producing tumours *in vivo* (DeFeo-Jones et al., 2002). In addition, the vinblastine-conjugate was shown to have a superior therapeutic index compared to the doxorubicin-conjugate, L-377202 (DeFeo-Jones et al., 2002). Clinical evaluation of this agent has yet to be reported. In another study, PSA-targeted TAPs have been developed incorporating the
potent SERCA pump inhibitor thapsigargin, the cytotoxicity of which is regardless of proliferative state and thus effective against characteristically slow growing prostate tumours (Denmeade et al., 2003). In agreement with previous approaches, thapsigargin-TAPs were selectively effective against PSA-producing prostate cells both in vitro and in vivo (Denmeade et al., 2003). Continuous administration of this TAP in vivo resulted in complete growth inhibition of PSA-producing prostate cancer xenografts but not PSA-negative renal carcinomas xenografts (Denmeade et al., 2003). This thapsigargin TAP is reportedly being evaluated in clinical trials for metastatic prostate cancer (Denmeade et al., 2003). The development of PSA-activated prodrugs has also been described for both paclitaxel and 5-fluorodeoxyuridine, although only in vitro results have been reported to date (Kumar et al., 2007; Mhaka et al., 2002).

The success of PSA-targeted chemotherapeutics has recently resulted in the expansion of the TAP concept into the biological arena, incorporating a bacterial cytolytic protein (aerolysin) rather than a chemotherapeutic effector (Williams et al., 2007). This PSA-activated protoxin (PRX302) when administered intratumorally in vivo caused minimal effect against PSA-null tumours, but complete remission of PSA-secreting tumour models. In addition, no toxicity was observed in organs adjacent to the prostate following intratumoral injection, supporting the specificity of this agent towards PSA. Clinical trials are currently underway to assess PRX302 as an intraprostatic treatment for recurrent prostate cancer (Williams et al., 2007).

**Tumour activated prodrugs directed to the Matrix Metalloproteinases (MMPs)**

To date, a small number of MMP-targeted prodrugs have been developed, most commonly towards the secreted family members MMP-2 and MMP-9 (Albright et al.,
One of the first studies to assess MMP-2 mediated tumour selective prodrug activation involved the incorporation of the alkylating agent melphalan into an MMP-2-cleaveable hexapeptide (termed MHP), a derivation of the TAP conjugate depicted in figure 1 (Timar et al., 1998). Although in vitro cytotoxicity of MHP proved disappointing, the melphalan effector was successfully liberated in the presence of MMP-2/9 and conditioned media from MMP-positive tumour cells, thereby supporting the potential for MMP targeted TAPs (Timar et al., 1998).

Subsequent strategies to develop MMP-targeted TAPs were based upon the structure outlined in figure 1, in which the effector therapeutic was conjugated to the terminus of the peptide sequence rather than being incorporated within it (as for MHP). One such TAP was a water-soluble maleimide derivative of doxorubicin, incorporating a peptide sequence suggested to be selectively cleaved by MMP-2 (Kratz et al., 2001; Mansour et al., 2003). In addition to having doxorubicin attached at one end of the conjugate, this TAP was also developed to bind to serum albumin, with the aim of using albumin as a macromolecular carrier to increase tumour accumulation of the TAP (Kratz et al., 2001; Mansour et al., 2003). Efficient activation of this TAP to release doxorubicin was demonstrated using both purified MMP-2 and MMP-2 positive tissue homogenates. In vivo, the maximum tolerated dose (MTD) for albumin-bound doxorubicin was substantially higher than for doxorubicin alone and subsequent studies showed superior activity against A375 melanoma at equitoxic doses (Mansour et al., 2003). The concept of macromolecular delivery of MMP-activated TAPs has also been investigated by several other groups with differing success (Chau et al., 2006a; Chau et al., 2006b; Chau et al., 2004; Tauro et al., 2005).
In contrast to the use of macromolecules as delivery vehicles, MMP-activated TAPs conforming to the simple ‘trigger-linker-effector’ structure, shown in figure 1, have shown significant potential as anticancer therapeutics. In one approach an anthraquinone topoisomerase inhibitor (NU:UB31) was linked to the C-terminus of an MMP-9 cleavable heptapeptide, and the N-terminus of the peptide was ‘capped’ with fluorescein isothiocyanate (FITC), to produce a TAP, EV1-FITC (Mincher et al., 2002; Van Valckenborgh et al., 2005; Young et al., 2003). The FITC in this prodrug allows for prodrug cleavage to be observed fluorescently, since the FITC is quenched by the anthraquinone in the intact TAP, a factor which is not present following TAP activation. Using a murine myeloma model, TAP metabolism in tissues ex vivo was higher in MMP-9 expressing tumour-bearing organs (bone marrow, spleen) relative to other tissues (heart, lung, kidney), as determined by fluorescence from FITC release (Van Valckenborgh et al., 2005). There was however a significant level of prodrug activation in non-diseased tissue homogenates, suggesting a lack of TAP specificity towards MMP-9 (Van Valckenborgh et al., 2005). An attempt to further increase MMP-selectivity was addressed using peptidomimetic analogues of TAPs, incorporating doxorubicin, auristatins and the duocarmycins (Kline et al., 2004). However, these peptidomimetic TAPs were either not activated by the MMPs or demonstrated no selective activity against MMP-positive versus MMP-negative cells. These studies suggest careful consideration of the effector molecule and the peptide sequence is paramount for the success of these TAPs.

In the most detailed study reported to date, MMP-targeted TAPs of doxorubicin were demonstrated to show a much higher therapeutic index than doxorubicin alone, using the MMP expressing HT1080 preclinical model (Albright et al., 2005). In this strategy the peptide length was shown to be central to both
compound stability and MMP-cleavage efficiency, with a heptapeptide containing three or four amino acids to the carboxy side of the scissile bond being optimal (depicted in Figure 3) (Albright et al., 2005). Similar to EV1-FITC, these prodrugs were capped on the free peptide end to prevent unrequired exopeptidase degradation (Figure 3). The optimised TAPs were activated by the secreted MMPs, MMP-2 and MMP-9, and the membrane-tethered MMP, MMP-14 (MT1-MMP), but not the endoprotease neprilysin, reinforcing their selectivity towards the MMP family. In an advancement of previous approaches, these TAPs were shown to be pharmacologically stable in vivo and preferentially metabolised in MMP-expressing tumours relative to heart and plasma, resulting in a 10-fold increase in the tumour/heart ratio relative to administration of doxorubicin alone (Albright et al., 2005). In addition, the optimised TAP resulted in an 80% cure rate against the HT1080 xenograft model, compared to only 10% with doxorubicin alone. One potential downside of this approach was that a significant fraction of leucine-doxorubicin (L-Dox) formed in the tumour, as a consequence of TAP-activation, was not rapidly metabolised to release doxorubicin (figure 3), allowing for diffusion of L-Dox away from the tumour to other tissues before conversion to doxorubicin, with potential consequences for induction of normal tissue toxicity (Albright et al., 2005). Further evaluation of these TAPS and their progression towards clinical trials has yet to be reported.

In addition to exploiting MMPs to activate cytotoxic agents linked to peptides, preliminary work has been undertaken to develop MMP-activated biotoxins, incorporating anthrax toxin, measles toxin, cytolysin, CD95-L and tumour-necrosis factor alpha (TNF-α) (Gerspach et al., 2006; Liu et al., 2000; Potrich et al., 2005; Springfield et al., 2006; Watermann et al., 2007). The strategy for these agents is
similar to that for MMP-activated cytotoxins in that the therapeutic moiety is bound to a MMP-cleavable sequence which acts to inactivate the agent until released selectively in the tumour. Although the potential for all these strategies was successfully demonstrated in vitro, antitumour data is only reported for the measles virus biotoxin, which demonstrated potent MMP-dependent activity (Springfeld et al., 2006)

Whilst a number of studies, outlined above, have endeavoured to harness the proteolytic power of the MMPs to selectively metabolise and thus activate TAPs, these attempts have in many cases not proved as fruitful as anticipated. The most likely explanation for this is the primary focus of strategies towards peptide conjugation of the ‘effector’ and the subsequent inactivation of this agent as a TAP rather than upon the design of the ‘trigger’ or peptide sequence. Determination of the optimal peptide sequence to facilitate both pharmacological stability in vivo and selective cleavage by the MMPs (or even specific MMP family members) is now known to be the most crucial and difficult step in design of TAPs against endoproteases, specifically the MMPs.

**Tumour Endoprotease Activated agents: The Future?**

As discussed herein, development of agents targeted towards the tumour by exploiting their increased endoprotease activity is an area of drug development showing great potential and promise. Several strategies and approaches have been evaluated with mixed results, all of which have led to a significant increase in our knowledge and understanding of this area. It is important to remember that in addition to these prodrugs improving tumour-selective delivery of cancer therapeutics, they function in parallel to reduce the unrequired activity of these agents against normal tissues,
including liver, heart and bone marrow. In this sense these TAPs could be developed to deliver agents to the tumour which in practise could not be delivered due to extensive normal tissue toxicities and a consequent narrow therapeutic index.

The determination of new endoprotease targets, protease substrates and overall substrate sequence requirements for individual proteases will be essential in the future development of TAPs. It is only once these enzyme requirements are fully understood that truly proficient and selective TAPs may be designed. Since proteases account for 2% of the human genome and regulate virtually every biological process, determining protease substrate specificities will be essential if TAPs are to be designed to be selectively activated by one only enzyme family, or indeed, one enzyme. Overlapping substrate specificities between protease families must be understood and addressed in the future design of these agents. In addition, improvements in our knowledge and understanding of other endoprotease systems overactive in cancer will further improve and increase the potential of this approach. In support of this, urokinase plasminogen activator (uPA), a serine endoprotease, was suggested as a valid target for TAP development (Romer et al., 2004), against which tumour-selective protoxins have been recently developed (Rono et al., 2006).

In summary, studies to date have demonstrated the worth of endoprotease targeted TAPs. Based on these encouraging studies, drug development strategies need to be accelerated to realise the clinical potential of these prodrugs.
Acknowledgements: The authors thank Paul Loadman and Robert Falconer for their help and encouragement with this research. The authors would also like to thank Jon Laye for critical review of this manuscript. This work was supported by Cancer Research UK (Programme grant A5953).

Conflict of Interest: The authors state no conflict of interest.
Figure Legends:

Figure 1  Schematic representation of tumour endoprotease activated prodrugs (TAPs). The prodrug is composed of three domains: a potent therapeutic agent (effector), an endoprotease cleavable peptide sequence (trigger), and a linker to join the trigger to the effector. This TAP remains inactive until activation of the trigger. The presence of the endoprotease in the tumour but not ‘normal’ tissues results in activation of the TAP trigger selectively in the tumour, causing the release of the potent effector and a subsequent therapeutic effect.

Figure 2  A) Structure of tumour-activated prodrug incorporating the microtubule-targeted agent vinblastine targeted at the serine protease, prostate specific antigen (PSA) (DeFeo-Jones et al., 2002). Vinblastine is attached at the 4-position to an octapeptide incorporating a PSA-selective cleavage site. The prodrug is endcapped by acetylation to prevent non-specific exopeptidase activation. B) Schematic representation of prodrug activation by PSA. The cleavage site for PSA within the peptide is indicated by the arrow. Following the initial cleavage by PSA the remaining amino acid residues are removed rapidly by exopeptidases.

Figure 3  A) Structure of MMP-targeted tumour-activated prodrug incorporating the cytotoxic agent doxorubicin (Albright et al., 2005). Doxorubicin is attached to a heptapeptide incorporating a MMP-selective cleavage site. The prodrug is endcapped by acetylation to prevent non-specific exopeptidase activation and promote in vivo drug stability. B) Schematic representation of prodrug activation by MMP with expected cleavage products. The cleavage site for MMP within the peptide is indicated by the arrow. Following the initial cleavage by MMP the remaining amino acid residues are removed rapidly by exopeptidases.
