Bose-Einstein condensation of $^{85}$Rb by direct evaporation in an optical dipole trap

Department of Physics, Durham University, Durham DH1 3LE, United Kingdom

(Received 29 March 2012; revised manuscript received 27 April 2012; published 30 May 2012)

We report a simple method for the creation of Bose-Einstein condensates of $^{85}$Rb by direct evaporation in a crossed optical dipole trap. The independent control of the trap frequencies and magnetic bias field afforded by the trapping scheme permits full control of the trapped atomic sample, enabling the collision parameters to be easily manipulated to achieve efficient evaporation in the vicinity of the 155 G Feshbach resonance. We produce nearly pure condensates of up to $4 \times 10^4$ atoms and demonstrate the tunable nature of the atomic interactions.

I. INTRODUCTION

The use of magnetically tunable Feshbach resonances [1] to control the interaction between atoms is now commonplace in many ultracold atomic gas experiments. The ability to precisely tune the s-wave scattering length, $a$, near a broad resonance has resulted in many exciting breakthroughs in the study of atomic Bose-Einstein condensates (BECs) and degenerate Fermi gases [2,3]. At the same time, narrow resonances have found applications in the coherent association of ultracold molecules [2,4], bringing quantum degenerate Fermi gases [2,3]. At the same time, narrow resonances have found applications in the coherent association of ultracold molecules [2,4], bringing quantum degenerate Fermi gases [2,3].

Section II describes the experimental setup, detailing the loading of the crossed dipole trap. In Sec. III we outline the evaporation scheme used to efficiently produce $^{85}$Rb. Section IV details the final parameters used to reach BEC. In Sec. V we demonstrate the tunable nature of the atomic interactions in the condensate before concluding and presenting our plans for future work in Sec. VI.

II. EXPERIMENTAL OVERVIEW

Central to our setup is a crossed dipole trap which we produce inside a ultra high vacuum (UHV) glass cell, shown in Fig. 1(a). Atoms are delivered to the cell via a magnetic transport apparatus, details of which can be found in Ref. [20]. The final stage of the delivery process is to transfer atoms into a static quadrupole trap (axial gradient 180 G cm$^{-1}$) constructed around the glass cell. The transport trap is then moved away from the glass cell to allow greater optical access. Typically the trapped atomic cloud contains $\sim 5 \times 10^5$ atoms at a temperature of $\sim 380$ μK. Forced radio frequency (RF) evaporation of the sample is then carried out. The optimized evaporation trajectory takes 26 s in total due to relatively slow rethermalization caused by the low s-wave scattering cross section in this temperature range [16]. However, we note that the linear potential produced by the quadrupole trap means it is possible to obtain runaway evaporation for a lower ratio of $a$ to $\ell$, though essentially all single-species alkali-metal atoms exhibit some sort of Feshbach spectrum, broad resonances suitable for tuning the scattering length are generally less accessible.

The difficulties associated with attempting to evaporatively cool $^{85}$Rb are well documented [10,16,17]. The elastic collision rate in samples trapped directly from a magneto-optical trap (MOT) is severely suppressed due to an unfortunately placed zero in the s-wave scattering cross section [16]. Additionally, the two- and three-body inelastic collision rates in ultracold samples are unusually high and vary strongly in the vicinity of the Feshbach resonance [17]. Nevertheless, carefully optimized evaporation in a weak Ioffe-Pritchard magnetic trap produced stable condensates of $\sim 10^4$ atoms [10]. However, with the development of optical trapping, the modern evaporator is equipped with a broader array of tools than her predecessor, allowing her to navigate the potential pitfalls associated with $^{87}$Rb with greater ease. For example, recent experiments [18,19] have almost circumvented these problems entirely by employing $^{87}$Rb to sympathetically cool low-density samples of $^{85}$Rb, yielding condensates of up to $8 \times 10^4$ atoms [18], at the expense of added experimental complexity.

Here we report a simple method for the creation of Bose-Einstein condensates of $^{85}$Rb by direct evaporation in a crossed optical dipole trap. The independent control of the trap frequencies and magnetic bias field afforded by the trapping scheme permits full control of the trapped atomic sample, enabling the collision parameters to be easily manipulated to achieve efficient evaporation in the vicinity of the 155 G Feshbach resonance. We produce nearly pure condensates of up to $4 \times 10^4$ atoms and demonstrate the tunable nature of the atomic interactions.

DOI: 10.1103/PhysRevA.85.053647 PACS number(s): 67.85.Hh, 03.75.Nt, 37.10.De
The crossed dipole trap is produced using a bow-tie arrangement of a single $\lambda = 1064$ nm beam with a total incident power of 10.1 W derived from a single-frequency fiber laser (IPG: YLR-15-1064-LP-SF). The beam is initially focused to $\sim 136 \mu$m. It then exits the cell and is refocused to produce an effective second beam of waist $\sim 125 \mu$m, crossing the first beam at 90°. The smaller waist compensates for reflection losses at the glass cell windows. The beams intersect $\sim 160 \mu$m below the quadrupole field zero to produce trap frequencies of $\omega_{x,y,z} = 2\pi \times (190, 160, 250)$ Hz at full power. Here $x$ and $y$ are along the dipole beams and $z$ is in the vertical direction. The dipole trap is switched on during the RF evaporation stage. To complete the loading, the quadrupole gradient is relaxed from 180 G cm$^{-1}$ to $\sim 21.5$ G cm$^{-1}$ in 500 ms. The final quadrupole gradient used is just less than that sufficient to support atoms against gravity ($\sim 22.4$ G cm$^{-1}$).

The presence of the magnetic gradient leads to weak magnetic confinement along the beams [22], enhancing the trap volume and resulting in a trap depth set by the vertical direction [Fig. 1(b)]. In addition, the offset from the field zero leads to a small magnetic field (~0.3 G) at the location of the crossed dipole trap. As the atoms are subject to both optical and magnetic confinement, we refer to this as the hybrid trap.

III. EVAPORATIVE COOLING

In order to reach the Feshbach resonance it is necessary to apply a moderate bias field ($\sim 155$ G). This leaves the trapped atoms still levitated against gravity; however, the confinement produced by the quadrupole trap along the dipole beams is effectively removed. Atoms now only remain at the intersection of the trap. This is our levitated crossed optical dipole trap. Before switching on the bias field, we first evaporate by ramping down the power of the hybrid trap at low field where inelastic losses are known to be low [23]. This allows us to exploit the enhanced volume of the hybrid trap to improve the transfer into the levitated crossed dipole trap. In contrast to the hybrid case, in the levitated trap evaporation happens preferentially along the dipole beams, as shown in Fig. 1(c), resulting in a trap with roughly half the depth compared to the zero-field case.

To achieve efficient evaporation in the levitated trap it is necessary to understand the interplay between elastic and inelastic collisions close to the Feshbach resonance. We explore this by indirectly probing the collision ratio, carrying out a fixed evaporation sequence for different magnetic fields. The efficiency, $\gamma$, of the evaporation sequence can then be calculated from the initial ($i$) and final ($f$) number, $N$, and PSD of the gas according to

$$\gamma = \frac{\ln(\text{PSD}_f / \text{PSD}_i)}{\ln(N_f / N_i)}.$$  

The efficiency for a 50 G window spanning the zero crossing of the Feshbach resonance is shown in Fig. 2(a). The two clear peaks at 161 G and 175–185 G highlight the most efficient fields at which to evaporate with the broad $a < 0$ peak, 175–185 G, giving marginally better performance. As $a$ approaches zero (red dashed line) the elastic collision rate reduces and rethermalization ceases. As a result the efficiency tends to zero and we see a corresponding peak in the fitted cloud temperature, Fig. 2(b).

The distinct structure evident in Fig. 2(a) follows from the magnetic field dependence of the elastic and inelastic collision rates. The elastic collision rate, determined by the
atomic scattering length shown in Fig. 2(c), varies by many orders of magnitude over the region of interest. Similarly, inelastic losses are known to exhibit a strong field dependence close to the resonance. Figure 2(d) shows the change in the three-body inelastic loss rate, $K_3$, measured close to the Feshbach resonance. It is apparent that for a given magnitude of scattering length the inelastic losses are marginally lower on the $a < 0$ side of the zero crossing, as previously predicted and observed [17,25]. This leads to slightly better evaporation performance for the 175–185 G peak [Fig. 2(a)].

IV. BOSE-EINSTEIN CONDENSATION

With this understanding of the collisional properties of the trapped cloud it is then clearer how best to achieve BEC in the optical trap. Following the low-field evaporation stage in the hybrid trap the bias field is ramped rapidly ($\sim$10 ms) to 175–185 G to exploit the window of efficient evaporation. It is at this low-loss region that the majority of the subsequent evaporation is carried out. Following a 500 ms evaporation ramp, the trap is compressed (in 1 s) by linearly increasing the dipole field is then ramped from 175 G to a new value in 10 ms. Following the low-field evaporation stage at $\sim$0 G, a 175–185 G bias field is applied. This produces the levitated trap (□) in which further evaporation is carried out. At a PSD of $\sim$0.5 the bias field is ramped to 161.3 G and a final evaporation stage is performed to reach BEC. Inset: Density profiles for (right to left) thermal, bimodal, and condensed atomic samples. (b) Horizontal cross sections of the condensate column density for a thermal (top), bimodal (center), and condensed (bottom) sample as the dipole beam power (top right) is reduced.

to $\sim$360 nK we are able to produce pure condensates with $\sim$4 × 10^4 atoms.

V. TUNABLE INTERACTIONS

In order to demonstrate the tunable nature of the condensate we present two simple experiments. In the first we alter the magnetic field synchronously with the release from the dipole trap and observe the variation of the expansion of the cloud following 55 ms of time of flight. As shown by the filled squares in Fig. 4(a) the change in mean field interaction strength with magnetic field manifests itself in a change in the cloud size. We see that the BEC reaches its minimum size as the scattering length approaches zero at 165.75 G [27], marked by the red, dashed line. Over the region of $a > 0$ the condensate number remains approximately constant. As $a$ becomes negative, the subsequent collapse [12] of the BEC causes an increase in cloud size. In comparison, when the

Following an initial evaporation stage at $\sim$0 G, a 175–185 G bias field is applied. This produces the levitated trap (□) in which further evaporation is carried out. At a PSD of $\sim$0.5 the bias field is ramped to 161.3 G and a final evaporation stage is performed to reach BEC. Inset: Density profiles for (right to left) thermal, bimodal, and condensed atomic samples. FIG. 4. (Color online) Tunable interactions. (a) Change in vertical size of a pure condensate (filled squares) and thermal cloud (open circles) as a function of magnetic field applied during time of flight. (b) Breathing mode oscillation set up by jumping the atomic scattering length from $\sim$315$a_0$ to $\sim$50$a_0$. The hold time shown is that at the new scattering length of $\sim$50$a_0$.

1An atomic sample at $\sim$0.15 $\mu$K is produced at 175 G. The magnetic field is then ramped from 175 G to a new value in 10 ms. Following the ramp, the trap is compressed (in 1 s) by linearly increasing the dipole beam power. This deepens the trap from 1.4 $\mu$K to 27.5 $\mu$K, increasing the atomic density and putting us well into the three-body-dominated loss regime. The lifetime of the atomic cloud in this new trap is measured and the three-body loss rate, $K_3$, determined from a fit to the atom number evolution with time [24].
same field jump is carried out using thermal atoms (for 25 ms time of flight) the comparatively low density leaves the cloud relatively insensitive to the atomic interactions and hence no change in shape is observed (open circles). The second, elegant demonstration of tunable interparticle interactions is to set up a breathing mode oscillation of the condensate by jumping the magnetic field, and hence scattering length, and observing the subsequent dynamics of the cloud at the new value of \( a \). The result for a jump from \( \sim 315 a_0 \) to \( \sim 50 a_0 \) is shown in Fig. 4(b). A jump of this type (to small \( a \) but \( a \neq 0 \)) in our almost spherically symmetric trap puts us well into the Thomas-Fermi regime and hence the resulting oscillation occurs at a frequency of \( \sqrt{5} \omega_{x,y} \). The trap frequency extracted using this model is in good agreement with the value measured by parametric heating.

VI. CONCLUSIONS AND OUTLOOK

In summary, we have presented the successful cooling of \(^{85}\text{Rb}\) to quantum degeneracy. BEC is realized using a crossed optical dipole trap with the addition of a magnetic field and a magnetic bias field to tune the atomic interactions. The atoms are cooled directly, without the need for any other refrigerant species, with pure condensates of \( 4 \times 10^6 \) atoms produced at 161.3 G. Our method is very similar in spirit to a scheme first developed to cool \(^{87}\text{Rb}\) to degeneracy [22] and subsequently extended to produce dual species condensates of \(^{87}\text{Rb}\) and \(^{133}\text{Cs}\) [29]. As such, we believe our method could be readily implemented in a number of experiments currently employing \(^{87}\text{Rb}\), broadening the scope for experiments with tunable interactions. However, we note that the choice of the dipole beam waists was key to the success of the trapping scheme. The high inelastic losses in \(^{85}\text{Rb}\) mean it is advantageous to keep trapping volumes large and trap frequencies weak. As a consequence, we found in early experiments using smaller beam waists (\( \sim 60 \mu\text{m} \)) we were unable to reach BEC.

In the future we plan to transfer the condensate into an optical waveguide in order to exploit the collapse shown in Fig. 4(a) to produce bright matter wave solitons [13,30,31]. These self-stabilizing wave packets are well localized due to attractive atom-atom interactions and hence show great potential as surface probes for the study of short-range atom-surface interactions [32]. Our apparatus includes a superpolished (surface roughness <1 Å) Dove prism [shown in Fig. 1(a)] for use in such experiments. In light of recent theoretical interest, there is also much scope for the study of binary soliton collisions [33,34] and the scattering of solitons from barriers [35,36] with a view to developing interferometry schemes utilizing bright-matter wave solitons.
