ABSTRACT
We have revisited the extended excursion set theory in modified gravity models, taking the chameleon model as an example. Instead of specifying their Lagrangian size, here we define the environments by the Eulerian size, chosen to be of the same order of the Compton length of the scalar field by physical arguments. We find that the Eulerian and Lagrangian environments have very different environmental density contrast probability distributions, the former being more likely to have high matter density, which in turn suppress the effect of the fifth force in matter clustering and halo formation. The use of Eulerian environments also evades the unphysical restriction of having an upper mass limit in the case of Lagrangian environments. Two methods of computing the unconditional mass functions, numerical integration and Monte Carlo simulation, are discussed and found to give consistent predictions.

Key word: large-scale structure of Universe.

1 INTRODUCTION
The excursion set theory (Bond et al. 1991) is a concise yet very successful approach (Zentner 2007) to study the non-linear structure formation in the standard cold dark matter (CDM) scenario. Starting from an (usually Gaussian) initial distribution of the density perturbation field at early times, with an evolution model such as the spherical collapse model,1 to map an initial density perturbation to a non-linear structure (dark matter halo) at some late time, it can predict statistically what fraction of matter has been assembled into the halo at that time. It makes the physics of structure formation clear and simple, and was a major tool for studying the large-scale structure formation when large cosmological simulations were still beyond the capability of supercomputers.

With the coming of the era of precision cosmology and progresses in supercomputing, N-body simulations (Bertschinger 1998) have become more common nowadays for its ability to capture non-linear evolution without any assumptions in the evolution model and hence more accurate predictions than the excursion set theory. Despite this, the analytical results of the latter still provide valuable information. For example, fitting formulae of the mass function can be obtained (Sheth & Tormen 2002), the parameters of which are then calibrated by the numerical simulations (Sheth & Tormen 1999; Jenkins et al. 2001; Tinker et al. 2008).

In many aspects, the study of the cause of the accelerated cosmological expansion (Copeland, Sami & Tsujikawa 2006) follows the same history of the enquiries of CDM: people first ask about their implications in the large, linear structures, and then gradually shift towards the smaller, non-linear scales, in which process ever advanced techniques and tools are developed. After an initial burst of theoretical or phenomenological models following the first observational evidences of the cosmic acceleration (Riess et al. 1998; Perlmutter et al. 1999), people have spent years trying to understand the behaviour of all these models on large scales (see, for example, Wang et al. 2000), paving the road that leads to a better and full understanding of the theories and preparing for the confrontations with future data.

One important class of such models involves modifications to Einstein’s general relativity (GR) on large scales (Jain & Khoury 2010; Clifton et al. 2012). Although these modified gravity models are mainly designed to explain the observations, many of the ideas are motivated from studies in fundamental physics, making them very appealing. Clearly, because GR has been tested rigorously in the laboratories and Solar system (Will 2006), any modifications to it must be strongly suppressed in the local environments and every successful modified gravity model must have some mechanisms to achieve this suppression to pass the first test. In this work, we will focus on a class of models where GR is modified by an additional dynamical scalar degree of freedom (a scalar field) which mediates a fifth force of gravitational strength between matter particles; the equation of motion (EOM) of this scalar makes it extremely heavy.

1 In this work, we only consider the spherical collapse model and focus on the effect of different definitions of environment on the halo mass function in modified gravity models.
and therefore hard to propagate, or extremely weakly coupled to matter, in regions of high matter density. In both cases, the fifth force is suppressed and therefore much weaker than gravity. The chameleon model of Khoury & Weltman (2004) and Mota & Shaw (2007) is a representative example. Chameleon models can have very rich phenomenology. In many cases, the background evolution can be indistinguishable from that of the standard ΛCDM paradigm (see e.g. Hu & Sawicki 2007; Brax et al. 2008; Li & Zhao 2009, for some examples). The linear perturbations on very large scales are unaffected by the fifth force either, because even in low-density environments the range of the fifth force is only of the order of Mpc (Li & Barrow 2007; Li & Zhao 2009) – which means that observables such as the cosmic microwave background spectrum and integrated Sachs–Wolfe effect are the same as the ΛCDM predictions. Finally, because of the strong suppression in the Solar system, there is no detectable deviation from GR locally. Consequently, the only place where we could expect to see effects of modified gravity would be the non-linear structures such as voids, clusters and galaxies, which are exactly the regime where numerical simulations are needed to make accurate predictions.²

Although a number of numerical simulations have already been done for such modified gravity models (Oyaizu 2008; Oyaizu, Lima & Hu 2008; Li & Zhao 2009, 2010; Schmidt et al. 2009; Li & Barrow 2011; Li & Hu 2011; Zhao, Li & Koyama 2011; Li et al. 2012a), they are still at a very early stage. The reason is that the equation governing the scalar field is generally very non-linear and it usually takes much longer to solve it than the standard Poisson equation of Newtonian gravity. Performing N-body simulations for modified gravity with very large box sizes and high mass/force resolutions is still a technical challenge, and this fact brings us back to the analytical methods, such as the excursion set theory.

Unfortunately, even the application of the excursion set theory becomes very non-trivial in the modified gravity theories. The non-linear equation essentially makes the behaviour of the scalar field (and the fifth force) sensitively dependent on the surrounding environment, and to determine the mapping from an initial overdensity to a late-time non-linear structure we need to have knowledge of the environments, which have very different densities and can at best be described by some probability distributions (see Brax, Rosenfeld & Steer 2010b, for an earlier study of such mapping). To solve this problem, Li & Efthathiou (2012) proposed an extension to the standard excursion set theory by solving the above mapping in some specific environments and then averaging over the probability distribution of the environments. An alternative way of viewing this approach is that the critical density for halo formation follows a distribution which depends on the environment density contrast – in the language of excursion set theory, the barrier is stochastic even though the collapse is described by the deterministic spherical collapse model. This stochasticity of barrier is in contrast to the one discussed in Maggiore & Riotto (2010a) and Corsaniti & Achitouv (2011) in the ellipsoidal collapse model, and we refer the readers to appendix C of Paranjape, Lam & Sheth (2012a) for the discussion regarding the scatter of critical density observed in numerical simulations and the stochasticity of barrier in the excursion set formalism.

The crucial component of the extended excursion set model is the environment: how do we define it? Obviously, different definitions may give rise to different environmental probability distributions, and there must be some physical arguments to motivate the definition. As a first example to illustrate the idea, Li & Efthathiou (2012) define the environment by fixing a Lagrangian (or initial comoving) size, which is the simplest possibility, surrounding each protohalo. As we shall discuss below, this definition has several drawbacks which can be cured by defining the environments as an Eulerian (physical) size.

This paper is organized as follows. In Section 2, we briefly review the theoretical model to be considered and summarize its main ingredients. We then discuss our new definition of environment and its motivation in Section 3. Section 4 is the main part of this work, which gives the numerical results of the unconditional mass function using both Lagrangian and Eulerian definitions of environments and discusses their difference; it also compares the two different methods of calculation – numerical integration and Monte Carlo simulation – and finds good agreement. The summary and conclusions of this paper can be found in Section 5.

## 2 THE CHAMELEON THEORY

This section lays down the theoretical framework for investigating the effects of coupled scalar field(s) in cosmology. We shall present the relevant general field equations in Section 2.1, and then specify the models analysed in this paper in Section 2.2.

### 2.1 Cosmology with a coupled scalar field

The equations presented in this subsection can be found in Li & Zhao (2009, 2010) and Li & Barrow (2011), and are presented here only to make this work self-contained.

We start from a Lagrangian density

\[
\mathcal{L} = \frac{1}{2} \left[ \frac{R}{\kappa} - \nabla^a \phi \nabla_a \phi \right] + V(\phi) - C(\phi) \mathcal{L}_{DM} + \mathcal{L}_S \tag{1}
\]

in which \( R \) is the Ricci scalar, \( \kappa = 8\pi G \), with \( G \) being the gravitational constant, \( \mathcal{L}_{DM} \) and \( \mathcal{L}_S \) are, respectively, the Lagrangian densities for dark matter and standard model fields. \( \phi \) is the scalar field and \( V(\phi) \) its potential; the coupling function \( C(\phi) \) characterizes the coupling between \( \phi \) and dark matter. Given the functional forms for \( V(\phi) \) and \( C(\phi) \), a coupled scalar field model is then fully specified.

Varying the total action with respect to the metric \( g_{ab} \), we obtain the following expression for the total energy momentum tensor in this model:

\[
T_{ab} = \nabla_c \phi \nabla_d \phi - \frac{1}{2} \left[ \nabla_c \nabla_d \phi - V(\phi) \right] + C(\phi) T_{ab}^{DM} + T_{ab}^S \tag{2}
\]

where \( T_{ab}^{DM} \) and \( T_{ab}^S \) are the energy momentum tensors for (uncoupled) dark matter and standard model fields. The existence of the scalar field and its coupling change the form of the energy momentum tensor, leading to potential changes in the background cosmology and structure formation. The coupling to a scalar field produces a direct interaction (fifth force) between dark matter particles due to the exchange of scalar quanta. This is best illustrated by the geodesic equation for dark matter particles:

\[
\frac{d^2 r}{d\tau^2} = - \nabla \phi - \frac{C(\phi)}{C(\phi)} \nabla \phi \tag{3}
\]
where \( \mathbf{r} \) is the position vector, \( t \) the (physical) time, \( \phi \) the Newtonian potential and \( V \) is the spatial derivative. \( C_\phi \equiv dC/d\phi \). The second term in the right-hand side is the fifth force and only exists for coupled matter species (dark matter in our model). The fifth force also changes the clustering properties of the dark matter.

To solve the above two equations, we need to know both the time evolution and the spatial distribution of \( \phi \), i.e. we need the solutions to the scalar field EOM:

\[
\nabla^2 \phi + \frac{dV(\phi)}{d\phi} + \rho_{DM} \frac{dC(\phi)}{d\phi} = 0, \tag{4}
\]

or equivalently

\[
\nabla^2 \phi + \frac{dV_{eff}(\phi)}{d\phi} = 0, \tag{5}
\]

where we have defined

\[
V_{eff}(\phi) = V(\phi) + \rho_{DM} C(\phi). \tag{6}
\]

The background evolution of \( \phi \) can be solved easily given the present-day value of \( \rho_{DM} \) since \( \rho_{DM} \propto a^{-3} \). We can then divide \( \phi \) into two parts, \( \phi = \bar{\phi} + \delta \phi \), where \( \bar{\phi} \) is the background value and \( \delta \phi \) is its (not necessarily small or linear) perturbation, and subtract the background part of the scalar field EOM from the full equation to obtain the EOM for \( \delta \phi \). In the quasi-static limit in which we can neglect time derivatives of \( \delta \phi \) as compared with its spatial derivatives (which turns out to be a good approximation on galactic and cluster scales), we find

\[
\nabla^2 \delta \phi = \frac{dC(\phi)}{d\phi} \rho_{DM} - \frac{dC(\bar{\phi})}{d\bar{\phi}} \bar{\rho}_{DM} + \frac{dV(\phi)}{d\phi} - \frac{dV(\bar{\phi})}{d\bar{\phi}}, \tag{7}
\]

where \( \bar{\rho}_{DM} \) is the background dark matter density.

The computation of the scalar field \( \phi \) using the above equation then completes the computation of the source term for the Poisson equation:

\[
\nabla^2 \phi = \frac{k}{2} [\rho_{tot} + 3 \rho_{\text{tot}}] = \frac{k}{2} [C(\phi) \rho_{DM} + \rho_B - 2V(\phi)], \tag{8}
\]

where \( \rho_B \) is the baryon density (we have neglected the kinetic energy of the scalar field because it is always very small for the model studied here).

### 2.2 Specification of model

As mentioned above, to fully fix a model we need to specify the functional forms of \( V(\phi) \) and \( C(\phi) \). Here we will use the models investigated by Li & Zhao (2009, 2010) and Li (2011), with

\[
C(\phi) = \exp(\gamma \sqrt{\phi}) \tag{9}
\]

and

\[
V(\phi) = \frac{\Lambda}{1 - \exp(-\sqrt{\phi})}. \tag{10}
\]

In the above, \( \Lambda \) is a parameter of mass dimension 4 and \( \gamma \) and \( \alpha \) are dimensionless parameters controlling the strength of the coupling and the steepness of the potentials, respectively.

We shall choose \( \alpha \ll 1 \) and \( \gamma > 0 \) as in Li & Zhao (2009, 2010), ensuring that \( V_{eff} \) has a global minimum close to \( \phi = 0 \) and \( d^2V_{eff}(\phi)/d\phi^2 \equiv m^2_\phi \) at this minimum is very large in high-density regions. There are two consequences of these choices of model parameters: (1) \( \phi \) is trapped close to zero throughout cosmic history so that \( V(\phi) \sim \Lambda \) behaves as a cosmological constant and (2) the fifth force is strongly suppressed in high-density regions where \( \phi \) acquires a large mass, \( m^2_\phi \gg H^2 \) (\( H \) is the Hubble expansion rate), and thus the fifth force cannot propagate far. The suppression of the fifth force is even stronger at early times, and thus its influence on structure formation occurs mainly at late times. The environment-dependent behaviour of the scalar field was first investigated by Khoury & Weltman (2004) and Mota & Shaw (2007), and is often referred to as the ‘chameleon effect’.

### 3 DISCUSSION ON ENVIRONMENT

The extended excursion set approach for chameleon models proposed in Li & Efstathiou (2012) differs from the original excursion set approach in the introduction of environment, which is important in the chameleon models for two reasons: first, the environmental density determines the critical density for the spherical collapse inside it; secondly, an arbitrary spherical overdense region does not reside in an environment with any density equally likely. As a result, in the language of excursion set theory, the calculation of the first-crossing probability of the critical density curve must now be done in different environments and then integrated over the distribution of the environment.

It is therefore evident that the specification of the environment is crucial in the extended excursion set approach. In Li & Efstathiou (2012), the environment is defined as follows:

1. it is a spherical region with a common centre as the considered spherical overdensity (i.e. the halo-to-be);
2. it is much bigger than the halo-to-be;
3. it is not too big because otherwise it will not give a faithful representation of the environmental density.

As a first approximation, Li & Efstathiou (2012) define the environment to have a Lagrangian radius of \( \xi = 8 h^{-1} \text{Mpc} \) and call this a fixed-scale environment approximation. This simplifies the numerical calculation and eliminates the need of Monte Carlo simulations.

However, the use of the Lagrangian radius \( \xi \) has certain drawbacks. As a first example, if the environment density is high (e.g. close to the critical density for collapse), then at late times the sizes of the environment and the halo-to-be could be roughly the same, violating the above requirement that the environment should be much bigger than the halo-to-be. As a second example, if the environmental density is low, then it expands faster than the cosmic expansion and at late times can become very large in size, no longer providing a faithful representation of the environment.

In Li, Zhao & Koyama (2012b), it has been shown, using numerical simulation results, that the analytical formula for the fifth force used in Li & Efstathiou (2012) is quite accurate, assuming that the environment has an Eulerian (rather than Lagrangian) radius \( \zeta = 5–8 h^{-1} \text{Mpc} \) (see fig. 2 there). As a result, a more physically reasonable definition of the environment is its Eulerian radius. As the characteristic length scale in the chameleon models is the Compton length \( \lambda_c \) of the scalar field (which is a function of time), a physical choice of the Eulerian radius \( \zeta \) of the environment would then be \( \zeta \sim O(\lambda_c) \) because matter field within \( \lambda_c \) is expected to affect the scalar field value at a point (this is the meaning of ‘environment’).

Of course, \( \lambda_c \) evolves (increases) in time, while \( \zeta \) could either increase or decrease depending on whether the environmental density is lower or higher than the cosmic average. One can certainly choose \( \zeta \sim \lambda_c \) throughout the evolution, but this will make the computation rather complicated. An alternative is to have \( \zeta \sim \lambda_c \) at
late times, say \( z = z_f \), where \( z_f \) is the formation redshift of haloes. This would mean that at early times \( \tau \) can be different from \( \lambda_C \), but there are two reasons to expect the overall effect to be small:

(i) the fifth force only becomes important at very late times in most chameleon models, and for redshift \( z > 2 \) it is mostly negligible. At low redshifts, the difference between \( \tau \) and \( \lambda_C \) is small;
(ii) even at early times, the difference between \( \tau \) and \( \lambda_C \) is big only for overdense environments which contract during the cosmic history, but for these environments the fifth force is weak throughout the whole cosmic evolution.

In this work, we shall choose \( \tau \) to be smaller than the Lagrangian environment \( \xi \) but of the same order as \( \lambda_C \). Because the environment is bigger than the range of the fifth force, its evolution could be approximated by the \( \Lambda \)CDM model. The Eulerian overdensity at time \( t \) can be related to the linearly extrapolated density contrast \( \delta(t) \) by the spherical collapse model (Bernardeau 1994; Sheth 1998):

\[
\Delta_{NL}(t) = \frac{m}{\bar{\rho} V} \approx \left[ 1 - \frac{\delta(t)}{\delta_{cr}} \right]^{-b_{sc}} \delta_{cr},
\]

where \( \delta_{cr} \approx 1.676 \) is the critical density for \( \Lambda \)CDM at \( z_f = 0 \), \( V \) is the Eulerian volume, \( m \) is the mass within this Eulerian volume and \( \bar{\rho} \) is the cosmic background density of matter.

The distribution of the environment density at a given Eulerian scale can be computed by the excursion set approach (Sheth 1998; Lam & Sheth 2008a; Paranjape, Lam & Sheth 2012b) using the spherical collapse model. Effectively, equation (11) defines a curve \( B(m) \) in the \( \delta-S \) plane (see below for definition of \( S \)). The first crossing of this environment barrier gives the value of the linear extrapolated density contrast \( \delta(t) \) that a spherical region containing mass \( m \) must have in order to evolve into an Eulerian volume \( V \) at \( t \):

\[
B(m) = \delta_{cr} \left[ 1 - \left( \frac{m}{\bar{\rho} V} \right)^{-1/\delta_{cr}} \right],
\]

where the enclosed mass is a function of \( S \) (see equation 14). The mapping between \( m \) and \( S \) depends on the linear matter power spectrum as well as the smoothing kernel. If a power-law matter power spectrum \( P(k) \) with the power index \( n_s \) is specified, then the above equation can be rewritten as

\[
B(S) = \delta_{cr} \left[ 1 - \left( \frac{\zeta}{8 h^{-1} \text{Mpc}} \right)^{3/8} \left( \frac{S}{\sigma_x^2} \right)^{3(3+n_s)/8} \right],
\]

where

\[
S(m) = S(\xi) = \frac{1}{2\pi^2} \int_0^\infty k^2 P(k) W^2(k\xi) \, dk,
\]

with \( W(k\xi) \) the filter function and \( \xi \) the Lagrangian radius of the filter so that \( m(\xi) = \frac{4}{3} \pi \xi^3 \bar{\rho} \). \( \sigma_x \) is given by \( S = \sigma_x^2 \), with \( \xi = 8 h^{-1} \text{Mpc} \). In particular for \( n_s = -1.2 \), this barrier becomes linear in \( s \) (approximating \( \delta_{cr} \approx 5/S \)) and make the analytical analysis easier. In what follows, we shall use \( \zeta = 5 h^{-1} \text{Mpc} \) as suggested by Li et al. (2012b). One can make a similar analogy for Lagrangian environments, only in this case the barrier is vertical (see Fig. 1) and there is one and only one crossing of this Lagrangian barrier.

In the language of excursion set theory, then, the first-crossing probability of the moving barrier \( B(S) \) in \( [S, S + dS] \), denoted by \( P_{env}(S) \, dS \), is the probability that an arbitrary point (the centre of a halo-to-be) is in an environment whose linearly extrapolated density contrast falls into \([B(S), B(S + dS)] \) and this environment will evolve into a region having an Eulerian radius \( \xi \) at \( z_f \); the total mass enclosed in this environment is \( m(S + dS) \leq M_{env} \leq m(S) \). Both the environmental density and environmental mass are important for the discussions below.

\fig{1}{An illustration of the Eulerian versus Lagrangian environments. See the text for a detailed description.}

\section{4 UNCONDITIONAL MASS FUNCTIONS}

As a first application of the idea described above, in the rest of the paper we shall study the (unconditional) mass function of the chameleon models, using both numerical integration and Monte Carlo simulations, assuming uncorrelated steps in the framework of the excursion set formalism. The analysis of correlated steps and the associated conditional mass function and halo bias will be discussed in Lam & Li (2012).

### 4.1 Eulerian versus Lagrangian environments

Fig. 1 illustratively demonstrates the difference between the two definitions of the environment (Eulerian and Lagrangian). Here, the dotted horizontal line denotes the critical density \( \delta_{cr} \approx 1.676 \) for a \( \Lambda \)CDM collapse, and the middle one of the dashed vertical lines represents the value of \( S \) corresponding to a Lagrangian radius \( \xi = 8 h^{-1} \text{Mpc} \), which was used in Li & Efstathiou (2012) as the definition of the (Lagrangian) environment. Consider now two random walk trajectories (the blue and red curves): they cross the middle vertical dashed line at the two dark grey filled triangles, but do not cross the dotted horizontal line before that. Those two triangles correspond to two very different values of \( \delta_{env} \) (1.3 and \(-0.4\)) and thus the two random walks represent structure formations in very different (Lagrangian) environments.

The Eulerian environment, on the other hand, is defined such that its Eulerian radius today is \( 5 h^{-1} \text{Mpc} \) and it is represented by the solid curve. The random walks cross this curve at the two grey filled circles, corresponding to \( \delta_{env} \approx 1.25 \) and 0.25, respectively: the environments are less different if they are Eulerian! In particular, the structure formation relevant for the red random walk now takes place in an overdense rather than underdense environment.

Note that the two filled circles correspond to Lagrangian radii of \( \xi = 10.3 \) and 5.43 \( h^{-1} \text{Mpc} \) (the left and right vertical dashed lines), respectively, while the two filled triangles correspond to Eulerian radii of \( \xi = 3.65 \) (dot–dashed curve) and 8.9 \( h^{-1} \text{Mpc} \) (dash–dotted–dot curve), respectively. It is clear that the Eulerian environment of the blue random walk contains about seven times more matter than that of the red random walk, but if one uses Lagrangian definition then both environments contain the same amount of matter.

The above result has implied that the Eulerian and Lagrangian environments should have different probability distribution functions (PDFs). We then need to compute the PDF of \( \delta_{env}, P(\delta_{env}), \)
for these environment definitions: the Lagrangian density contrast follows the Gaussian distribution and the corresponding \( P(\delta_{\text{env}}) \) is given by equation (40) of Li & Efstathiou (2012), while the Eulerian density can be considered as a mixture of Lagrangian density from different smoothing scales: a dense Eulerian environment is evolved from a bigger Lagrangian batch but the opposite is true for underdense Eulerian environments.

There are different methods to calculate \( P(\delta_{\text{env}}) \) for the Eulerian environment: one can obtain it either by solving the first-crossing distribution of the barrier in equation (12) (see Zhang & Hui 2006; Lam & Sheth 2009, for uncorrelated steps; Maggiore & Riotto 2010b; Corasaniti & Achitouv 2011; Ma et al. 2011; Musso & Sheth 2012; Paranjape & Sheth 2012; Paranjape et al. 2012a, for correlated steps) or using analytical expressions such as the log-normal distribution or the expressions given in Lam & Sheth (2008a,b) for the evolved non-linear density contrast and combining that with equation (11) to obtain \( P(\delta_{\text{env}}) \) (recall that \( \delta_{\text{env}} \) is the linearly extrapolated density contrast at the Eulerian environment). In particular, for power-law matter power spectrum the barrier is given by equation (13), and applying the first-crossing probability approximation in Lam & Sheth (2008a) (see Lam & Sheth 2009, for an explanation for this approximation), the distribution of \( \delta_{\text{env}} \) is

\[
P(\delta_{\text{env}}) = \frac{\beta^{1/2}}{\sqrt{2\pi}} \left[ 1 + (\omega - 1) \frac{\delta_{\text{env}}}{\delta_c} \right] \left( 1 - \frac{\delta_{\text{env}}}{\delta_c} \right)^{-\omega/2-1} \times \exp \left[ -\frac{\beta^2}{2} \left( 1 - \frac{\delta_{\text{env}}}{\delta_c} \right)^2 \right],
\]

where \( \beta = (\xi/8)^{1/3}/a^{2/3}, \omega = \delta_c, \gamma \) is the logarithmic derivative of the density fluctuation variance with respect to \( m \):

\[
\gamma = \frac{\partial \ln \delta}{\partial \ln m} = n_s + 3/2.
\]

The two environment density distributions for the case of power-law power spectrum with \( n_s = -1.5 \) are shown in Fig. 2, which shows the PDF for the Eulerian environment peaks at bigger \( \delta_{\text{env}} \) than that for the Lagrangian environment. The results were computed numerically using the method described in Zhang & Hui (2006) and used in Li & Efstathiou (2012). We note the following.

(i) If \( \delta_{\text{env}} \) is close to \( \delta_{\text{sc}} \), the PDF is smaller for the Eulerian environment, because for such an environment to evolve into an Eulerian radius of 5 h^{-1} \text{Mpc} today, it must have an extremely large Lagrangian size \( \xi \gg 8 h^{-1} \text{Mpc} \), which is a very rare event. Note that the other reason is due to the approximation formula equation (11) – it maps \( \delta_{\text{lin}} \rightarrow \delta_c \) to \( \delta_{\text{env}} \rightarrow \infty \). Hence, \( P(\delta_{\text{env}}) \) must go to zero for \( \delta_{\text{env}} \geq \delta_c \).

(ii) The PDF for Lagrangian environment peaks at \( \delta_{\text{env}} \approx 0 \), because at any value of \( S \) (say \( S = 0.64 \) for \( \xi = 8 h^{-1} \text{Mpc} \), middle vertical dashed line of Fig. 1) the value of the random walk position satisfies a Gaussian distribution.

(iii) The PDF for Eulerian environment peaks at \( \delta_{\text{env}} \approx 0.8 > 0 \), because the random walk is crossing a decreasing barrier. This means that if one integrates over the PDF of environments then more contributions come from higher density environments under the Eulerian definition.

(iv) The PDF is lower for small \( \delta_{\text{env}} \ (< -1.5) \) under the Lagrangian definition, because underdensities with linearly extrapolated density contrast \( \delta < -1.5 \) and Lagrangian size \( \xi = 8 h^{-1} \text{Mpc} \) will have evolved into very large Eulerian sizes today \( (\xi \gg 5 h^{-1} \text{Mpc}) \) and this is rare event; in contrast, to have an Eulerian size of 5 h^{-1} \text{Mpc} today, such underdensities can be quite small in initial sizes whose rms fluctuation is bigger and hence the probability is not negligible.

4.2 Spherical collapse in a given environment

The spherical collapse history of an initial overdensity in a given environment of linearly extrapolated density contrast \( \delta_{\text{env}} \) has been discussed in detail in Li & Efstathiou (2012), to which interested readers are referred, and here we will only give a qualitative description of the results.

Fig. 3 shows the critical density \( \delta_c(S, \delta_{\text{env}}) \) for an initial overdensity to collapse at \( z_t = 0 \), as a function of both \( S \) and \( \delta_{\text{env}} \). As the fifth force is always attractive, \( \delta_c(S, \delta_{\text{env}}) < \delta_{\text{sc}}, \) where \( \delta_{\text{sc}} \) is the

![Figure 2](http://mnras.oxfordjournals.org/)  
*Figure 2*. The probability distribution, \( P(\delta_{\text{env}}) \), of the Eulerian (solid curve) and Lagrangian (dashed curve) environments, normalized to unity.

![Figure 3](http://mnras.oxfordjournals.org/)  
*Figure 3*. The critical density for the spherical collapse at \( z_t = 0 \), as a function of the linearly extrapolated environmental density contrast \( \delta_{\text{env}} \) and \( S \).
critical density if the fifth force vanishes. Furthermore, we note the following.

(i) In high-density environments ($\delta_{\text{env}} \rightarrow \delta_c$) the fifth force is strongly suppressed so that the collapse is governed by Newtonian gravity only and $\delta_i \approx \delta_c$.

(ii) As $\delta_{\text{env}}$ decreases, the fifth force becomes stronger in general and enhances the matter clustering. This means that the required critical density to collapse at $z_i$ is lower.

(iii) Very small values of $S$ correspond to the very big smoothing scales. Such regions have efficient self-screening of the fifth force irrespective of their environment, and hence $\delta_i(S, \delta_{\text{env}}) \approx \delta_c$ for arbitrary $\delta_{\text{env}}$ for small $S$.

(iv) Large values of $S$ correspond to small smoothing scales, which does not have strong self-screening of the fifth force, and hence $\delta_i(S, \delta_{\text{env}})$ depends sensitively on $\delta_{\text{env}}$.

In practice, once we know $\delta_{\text{env}}$, we can fully determine the collapse criteria for haloes of arbitrary size in this environment, and therefore the first-crossing probability density, $f(S|\delta_{\text{env}})$, across the barrier $\delta_i(S, \delta_{\text{env}})$. Here $\delta_i$ denotes it is the conditional first-crossing probability that the random walks having first crossed $B(S)$ given in equation (13) at $B(S) = \delta_{\text{env}}$. One then only needs to average over the first-crossing probability distribution of $\delta_{\text{env}}$ (which we have found in the previous subsection) to find the averaged first-crossing probability $f(S)$.

### 4.3 Averaging over environmental distribution

As in Li & Efstathiou (2012), the final first-crossing probability, which is related to the unconditional mass function, is calculated by making the environmental average:

$$f(S) = \int_{-\infty}^{\delta_c} f(S|\delta_{\text{env}}) P(\delta_{\text{env}}) d\delta_{\text{env}}, \quad (18)$$

where the upper limit of the integral is $\delta_c$ because $\delta_{\text{env}} \leq \delta_c$ (cf. Fig. 2) because by definition an environment has not collapsed to form a halo by $z_i$. In the case of Lagrangian environment, $P(\delta_{\text{env}})$ is defined so that it is identically zero for $\delta_{\text{env}} \geq \delta_c$, as shown in equation (40) of Li & Efstathiou (2012). For the Eulerian environment proposed in this work, the Eulerian barrier always lies below $\delta_c$ for all $S > 0$, hence this upper limit is valid by construction.

The mass function, $dn/dM$, is related to $f(S)$ by

$$\frac{dn}{dM} = \frac{\bar{n}}{M} f(S) \frac{ds}{dM} \frac{dM}{dS} dS, \quad (19)$$

where $n$ is the number density of haloes and $M$ the halo mass. In the literature, an alternative quantity which is often used is the collapsed mass fraction $v F(v)$, with $v = \frac{\delta_c}{S}$, $vF(v)$ is the fraction of matter in collapsed objects per logarithmic interval of $v$ and satisfies

$$F(v) dv = f(S) dS \Rightarrow v F(v) = S f(S). \quad (20)$$

In the following subsections, we shall calculate the quantity $v F(v)$ using two methods: the numerical integration of equation (18) and Monte Carlo simulations. We focus on the excursion set with uncorrelated step in the current study but would like to point out that equation (18) applies in both correlated and uncorrelated steps calculation – in the case of correlated steps, one must take into account the fact that the condition in $f(S|\delta_{\text{env}})$ is the random walk first crosses the environment barrier at $\delta_{\text{env}}$, or in other words the random walk is non-Markovian. It complicates the analytical calculation and it will be discussed in Lam & Li (2012). In the present case, where

the random walk has uncorrelated steps (it is Markovian), the conditional probability does not depend on the history of the walk prior to $\delta_{\text{env}}$.

In what follows, we apply two approaches to evaluate the halo mass function in modified gravity models. The numerical integration approach is similar to the previous work by Li & Efstathiou (2012), which applies the method in Zhang & Hui (2006); the Monte Carlo simulation approach follows the variation of density contrast as a function of smoothing scale and we keep tracks of the first crossing of the environment barrier as well as the first crossing of the consequent modified halo formation barrier.

#### 4.3.1 Numerical integration

As numerical examples, we have calculated $v F(v)$ as a function of $v$ for three models – GR and two chameleon models with $\mu = 0.5$, $\alpha = 10^{-6}$ and $\alpha = 10^{-5}$ – all having the same background cosmology. A power-law matter power spectrum with index $n_s = -1.5$ is assumed. For each model, we have done the calculation assuming Lagrangian and Eulerian environments, respectively, and the results are shown in Fig. 4.

Assuming spherical collapse, there is no environmental dependence in the $\Lambda$CDM result, which means that the prediction of $v F(v)$ should be the same whether one uses the Lagrangian or Eulerian definition of environment. This has been confirmed in the upper left-hand panel of Fig. 4, which serves as a check of accuracy of the numerical computation. For comparison, we have also plotted the exact analytic solution for the $\Lambda$CDM model (solid curve):

$$F(v) = \sqrt{\frac{v}{2\pi}} \exp \left( -\frac{v^2}{2} \right). \quad (21)$$

In Fig. 2, we have seen that the PDF for Eulerian environment peaks at higher $\delta_{\text{env}}$ than the PDF for Lagrangian environment. Because higher environmental density means stronger suppression and therefore weaker effect of the fifth force, we would expect that the deviation from $\Lambda$CDM prediction of $v F(v)$ is smaller if we use the Eulerian instead of Lagrangian definition of environment. This is confirmed by Fig. 4, which shows that the former gives smaller $v F(v)$ for medium and large $v$ (haloes of medium and large sizes).

For small values of $v$, on the other hand, $v F(v)$ is bigger if one uses Eulerian environment, because a smaller fraction of matter has fallen into medium and large collapsed haloes compared to the case of Lagrangian environments, and therefore more matter is left to form the isolated small haloes.

Note that one disadvantage of using a (fixed-sized) Lagrangian radius, as in Li & Efstathiou (2012), is that all the environments have exactly the same initial size and so contain the same amount of matter. In particular, the biggest halo to form in any given environment cannot contain more matter than that is contained in the environments, and this places an upper limit of the halo mass, as is shown in Fig. 4. If one uses Eulerian environment, this problem is solved because the environment can be arbitrarily large in size.

#### 4.3.2 Monte Carlo simulations

In this subsection, we compare the first-crossing distribution for different models with or without the chameleon fifth force using

---

3 We will consider GR with a cosmological constant which drives the accelerating expansion of the Universe. Therefore, in what follows, we will use the words ‘GR’ and ‘$\Lambda$CDM’ interchangeably.
Monte Carlo simulations. It is customary to use the variance in equation (14) with a top-hat window function to relate $S$ and the smoothing scale $R$, although strictly speaking it is not fully consistent since random walks with the top-hat window function induce correlated steps (or one needs to use the sharp $k$-space window function – which does not have a well-defined enclosed mass – to obtain uncorrelated steps; Bond et al. 1991).

In the Monte Carlo simulations, a sample of random walks is generated following the procedure in Bond et al. (1991). In hierarchical models, the variance of the density field is a monotonic function of $\delta$, and, in this case, it is possible, though rare, that the random walk reaches inside it. On the other hand, if one uses Lagrangian environments, the environment density for Eulerian environment is determined using this environment average (see the text) is performed assuming Lagrangian and Eulerian environments, respectively (see the legends), and the solid curve is the analytic result for ΛCDM. Upper right-hand panel: the same as the upper left-hand panel, but here only the results for a chameleon model with $\alpha = 10^{-6}$, $\mu = 0.5$ (the symbols) are shown; the analytical results for ΛCDM is shown as a solid curve for comparison. Lower left-hand panel: the relative difference of $vF(\nu)$ between the chameleon model with $\alpha = 10^{-6}$ and ΛCDM. Lower right-hand panel: the relative difference of $vF(\nu)$ between the chameleon model with $\alpha = 10^{-5}$ and ΛCDM. Note that the vertical axis is $\ln(10)vF(\nu)$ rather than $vF(\nu)$.

Fig. 5 compares the output of the Monte Carlo simulations to that from the numerical integration described in the previous subsection. For this purpose, we have only plotted the ΛCDM model and a chameleon model of $\mu = 0.5, \alpha = 10^{-6}$, adopting the Eulerian definition of the environment with a radius of $5h^{-1}\text{Mpc}$. The predicted mass functions from the two methods agree with each other reasonably in both models and, in the former case, they are consistent with the analytical result as well.

As Monte Carlo simulations with uncorrelated steps are generally much faster than the numerical integration, we shall use the former to test the effects of different physical parameters. Figs 6 and 7 show the dependency of the collapsed mass fraction $vF(\nu)$ on the...
Excursion set in modified gravity reload

5 Discussions and Conclusions

For modified gravity models which reduce to Newton gravity in high-density environments such as the Solar system, while at the same time have significant deviations from GR on Mpc scales, the environment is often an important concept in both the theory and the techniques used to analyse it. In this paper, we extended the work of Li & Efstathiou (2012) on estimating the modification of halo abundance in chameleon models within the framework of the excursion set approach by considering the possibility of defining environments according to their Eulerian, rather than Lagrangian, sizes. Being the physical size, the Eulerian size changes with time and describes the dynamical nature of the true environment. By choosing the Eulerian size to be of the same order as the Compton length of the scalar field, the single length scale in the theory, we have a better motivated definition of the environments.

(i) Increasing the radius of the Eulerian environment results in more big haloes because it necessarily means that the PDF of the initial environment density $\delta_{\text{env}}$ shifts towards lower values of $\delta_{\text{env}}$, making the formation of such haloes more strongly affected by the fifth force. This dependence on the Eulerian environment radius is subdominant compared to the modification to the GR case.

(ii) The effect of the Eulerian environmental radius on the abundance of small haloes is weaker.

(iii) Switching to a Lagrangian environment results in a distinctive drop in intermediate-mass halo – this decrease corresponds to the Lagrangian scale chosen: beyond $\log(\nu) = 0.63$ our Lagrangian environment chameleon models revert to the GR mass function.

(iv) The results using a $\Lambda$CDM matter power spectrum are similar to the power-law power spectrum with $n_s = -1.5$.

(v) Increasing $\alpha$ weakens the chameleon effect which suppresses the fifth force in high matter density regions, and thus producing more large haloes.

5 Discussions and Conclusions

For modified gravity models which reduce to Newton gravity in high-density environments such as the Solar system, while at the same time have significant deviations from GR on Mpc scales, the environment is often an important concept in both the theory and the techniques used to analyse it. In this paper, we extended the work of Li & Efstathiou (2012) on estimating the modification of halo abundance in chameleon models within the framework of the excursion set approach by considering the possibility of defining environments according to their Eulerian, rather than Lagrangian, sizes. Being the physical size, the Eulerian size changes with time and describes the dynamical nature of the true environment. By choosing the Eulerian size to be of the same order as the Compton length of the scalar field, the single length scale in the theory, we have a better motivated definition of the environments.

Of course, the exact value of the Eulerian size $\xi$ is still a free parameter which can be tuned to match the simulation data. Alternatively, one can make certain approximations in the calculation to obtain the functional form of the mass function and then calibrate the parameters using simulations. Another possible solution is by applying correlated steps in the excursion set approach (see Lam & Li 2012) – dramatic fluctuations between similar smoothing scales are unlikely with correlated steps and may be able to evade this ambiguity in the choice of Eulerian size.

The Lagrangian definition of environments also suffers from a limitation, namely that all environments, having the same initial
\[ \alpha = \text{derive approximate analytical expression for the halo mass function such as the halo bias, voids statistics and merger tree.} \]

We can also use this framework, we can easily analyse other quantities of interests, (Hinterbichler & Khoury 2010; Davis et al. 2012) modes. Within the framework, the effect of different definitions in the chameleon models. Results are obtained from Monte Carlo simulations with \( \Lambda CDM \) power spectrum where ratios of mass function are taken with respect to that of Eulerian environment \( \xi = 5.6^{-1} \) Mpc (red solid curve in Fig. 6). Three other chameleon models are considered: Lagrangian environment with \( \xi = 8 h^{-1} \) Mpc (green boxes); Eulerian environment with \( \xi = 8 h^{-1} \) Mpc (blue dotted curves) and with \( \xi = 10 h^{-1} \) Mpc (magenta dashed curves). Left-hand panel: chameleon model with \( \mu = 0.5, \alpha = 10^{-5} \); right-hand panel: \( \mu = 0.5, \alpha = 10^{-5} \). Only errors bars for Lagrangian environment with \( \xi = 8 h^{-1} \) Mpc (green boxes) are shown for clarity.

In our theoretical framework, the effect of different definitions of the environment enters into the calculation through the change in the PDF of \( \delta_{\text{env}} \), which describes the distribution of density contrast in the environment surrounding halo. Since the strength of the fifth force depends on \( \delta_{\text{env}} \), modifications in \( \rho(\delta_{\text{env}}) \) alters the halo abundance for different environment definitions. In particular, we found that it is more likely to have high values of \( \delta_{\text{env}} \) in Eulerian environment. In this case, the fifth force is suppressed and the net result is smaller deviation of the mass function from \( \Lambda CDM \) predictions, especially for the big and medium-sized haloes. We have verified this using two methods: numerical integration and Monte Carlo simulations, and both methods agree with each other.

To briefly summarize, this work emphasizes the importance of environment definition in the study of structure formation in modified gravity theories, and lays down the formalism for applying a physically motivated Eulerian environment in the framework of the excursion set approach. This framework could easily be generated to other types of modified gravity theories, such as the environmentally dependent dilation (Brax et al. 2010a, 2011) and the symmetron (Hinterbichler & Khoury 2010; Davis et al. 2012) modes. Within this framework, we can easily analyse other quantities of interests, such as the halo bias, voids statistics and merger tree. We can also derive approximate analytical expression for the halo mass function and calibrate the parameters with the numerical simulations. These will be the topics of future works.
