(Dated: December 1, 2015)

We review experimental and theoretical aspects of CP violation in the $B^0_s$-system. In that respect we present updates for the mixing parameters of the $B^0_s$ mesons expected in the Standard Model (SM): the mass difference $\Delta M_{s}^{\text{SM}} = (18.3 \pm 2.7) \text{ ps}^{-1}$, the decay rate difference $\Delta \Gamma_{s}^{\text{SM}} = (0.085 \pm 0.015) \text{ ps}^{-1}$, the flavour specific CP asymmetry $a_{s}^{\text{SM}} = (2.22 \pm 0.27) \cdot 10^{-5}$ and the equivalent quantities in the $B^0$-sector. The experimental measurements of $\Delta M_s$ and $\Delta \Gamma_s$ are more precise and agree very well with the predictions, which can also be viewed as a proof of theoretical tools, like the Heavy Quark Expansion (HQE). CP violating studies in the $B^0_s$ system provide essential information to test the SM expectations. Mixing quantities can be used to study model independent bounds on new physics (NP) effects, yielding the familiar picture: the standard model (SM) gives the dominant contribution, while there is still some sizable space for NP effects. In the case of $\Delta M_s$ effects of the order of 15% are not excluded. In the CP phase $\phi_s$ due to CP violation in the interference of decays and mixing $\mathcal{O}(100\%)$ effects are still possible. The semi-leptonic CP asymmetry $a_{s}^{\text{SL}}$, which is due to CP violation in mixing, could still be a factor of 250 larger than its robust SM expectation and thus provides a very clean observable for NP searches. We comment in detail on theoretical improvements that are necessary to make full use of the experimental precision.

I. INTRODUCTION

The phenomenon of CP violation, discovered more than 50 years ago ([Christenson et al. 1964]), is an essential ingredient to explain the apparent imbalance between matter and anti-matter in the Universe ([Sakharov 1967]). Consequently, this topic attracts a lot of attention. In the Standard Model ((SM) [Glashow 1961, Salam 1968, Weinberg 1967]) CP violation arises in the Yukawa-sector via quark mixing and it is described by a complex parameter in the Cabibbo-Kobayashi-Maskawa
matrix (CKM-matrix; Cabibbo 1963, Kobayashi and Maskawa 1973). Intensive studies of CP violation, especially at the $e^+e^−B$ factories (see e.g. Bevan et al. 2014 for a comprehensive review), provide convincing evidence that the main source of CP violation, describing the currently available particle physics data is the complex phase of the CKM-matrix. More precisely, the results of various measurements performed in completely different experimental environments (different energies, experiments, accelerators, processes etc.) do not contradict to the unitarity of the CKM matrix, see (Ambizz et al. 2014). This observation results in the statement that the single complex phase of the $3 \times 3$ CKM-matrix is currently sufficient to describe the multitude of CP-violating phenomena observed by experiments.

However, this tremendous success is spoiled by the cosmological observation put forward in several theoretical works, that CP violation provided by the CKM mechanism is not sufficient to explain the observed abundance of matter in the Universe. The most recent discussion of this problem can be found in (Bambi and Dolgov 2015). Thus, the absence of anti-matter in our world demands the existence of additional sources of CP violation beyond the SM. The efforts of many past and present particle physics experiments are directly related to the search of these new sources. Such a quest may result in the explanation of the baryon asymmetry in the universe and at the same time in the detection of new physics beyond the SM. These considerations explain an increased interest in CP violation studies.

In this respect, the study of CP violation in the $B^0_s$ system offers an excellent opportunity to detect possible deviations from SM predictions. The current level of theoretical understanding of the $B^0_s$ system is good enough to predict SM phenomena for the $B^0_s$ meson with a reasonable precision. Moreover, the Standard Model CP violating effects are expected to be suppressed in comparison to CP violation in $B^0$ meson decays. Therefore, even a relatively small contribution of new physics effects could be clearly visible in the $B^0_s$ system, see e.g. (Dunietz et al. 2001) for an early reference pointing this potential for a Null-test. More precisely, the angle $\beta$ describing CP violation in interference of decay and mixing in the $B^0$ system is predicted to be of the order of 22°. The corresponding angle $\beta_s$ in the $B^0_s$ system is expected to be about 1° only. Thus, a contribution of physics beyond the SM even at the level of 1° could be clearly visible in the $B^0_s$ system.

Unfortunately the contribution of the so-called penguin effects to the measured value of $\beta_s$ could also be $\sim 1°$. Therefore a measurement of 2° or 3° for this angle (which is still possible within the current experimental uncertainties) would not necessarily be an unambiguous signal for new physics. Here a more precise determination of penguin contributions is mandatory (Aaij et al. 2015c).

On the contrary, solid conclusions about the existence of new physics could be drawn by the investigation of CP violation in mixing extracted from semi-leptonic charge asymmetries. Here a measured value of about two or three times the value of the SM predictions would be an unambiguous signal for new physics.

The $B^0_s$ meson is produced with a small cross section at $e^+e^−B$-factories. The working c.m.s. energy of both the BaBar and Belle experiments is the mass of the $\Upsilon(4S)$ meson and $B^0_s$ mesons are not produced in its decays. The study of $B^0_s$ mesons is possible only by running at the mass of the $\Upsilon(10860)$ meson, which is not the primary goal of both $e^+e^−$ experiments. At a later stage, the Belle experiment took some data at this increased energy and obtained several interesting results, notably some branching fractions of $B^0_s$ decays, see e.g. (Olive et al. 2014). However, the contributions of this experiment to CP violation studies of the $B^0_s$ system are still quite limited. So far, the main source of information on $B^0_s$ meson comes from the hadron collider experiments at Tevatron (CDF, D0) and LHC (ATLAS, CMS, LHCb). In particular LHCb, the first experiment designed to study beauty and charm decays at LHC, has produced an impressive body of data on CP violation in $B^0_s − B^0_s$ mixing and decay.

This paper aims to summarise the current experimental knowledge of CP violation in the $B^0_s$ system along with their theoretical interpretation. It is organised as follows. Section II provides the summary of the main properties describing the $B^0_s$ system, such as the mass and width difference, together with their SM predictions and experimental measurements, as well as the time evolution of the $B^0_s$-system. Here a special emphasis is given to the theoretical uncertainties. Section III gives the theoretical description and the experimental results of CP violation in $B^0_s-B^0_s$ mixing. $\gamma$ CP violation in interference of $B^0_s$ mixing and decay is discussed in Section IV with a detailed review of penguin contributions, while Section V describes the results of studies of CP violation in the $B^0_s$ decays, and the methods to derive the CKM angle $\gamma$ from $B^0_s$ decays. Section VI contains a discussion of the obtained results in the context of physics beyond the Standard Model and a derivation of model independent constraints on new physics contributions, which can be inferred from a study of the $B^0_s$ system. Finally, Section VII gives an outlook to future developments in this very active field of particle physics. In the appendix details of the numerical updates of the Standard Model predictions for the mixing quantities are listed.
II. THE $B^0_S$ SYSTEM

A. Theory: Basic mixing quantities, time evolution of the $B^0_S$ system and the HQE

The quantum mechanical time evolution of a decaying particle $B$ with mass $m_B$ and lifetime $\tau_B = 1/\Gamma_B$ is given as

$$|B(t)\rangle = e^{-i m_B t - \frac{E_B}{\hbar} t} . |B(0)\rangle,$$

where $\Gamma_B$ denotes the total decay rate of the $B$ particle. Considering now the system of neutral $B_s$ mesons, defined by their quark flavour content $|B^0_s\rangle = |(\bar{b} s)\rangle$, and their anti-particles, $|\bar{B}_s^0\rangle = |(\bar{b}\bar{s})\rangle$, we can write down the time-evolution as a simple differential equation for a two-state system:

$$i \frac{d}{dt} \left( \begin{array}{c} B^0_s(t) \\ \bar{B}^0_s(t) \end{array} \right) = \left( \begin{array}{cc} M^s - i \frac{\Gamma^s}{2} & -i \frac{\Gamma^{s\bar{s}}}{2} \\ i \frac{\Gamma^{s\bar{s}}}{2} & M^{\bar{s}} + i \frac{\Gamma^{s\bar{s}}}{2} \end{array} \right) \left( \begin{array}{c} B^0_s(t) \\ \bar{B}^0_s(t) \end{array} \right).$$

Naively one expects the diagonal entries of the $2 \times 2$ matrix $M^s$ to be equal to the mass of the $B^0_s$ meson, $M^s$, the diagonal entries of $\Gamma^s$ to be equal to the decay rate of the $B^0_s$ meson, $\Gamma^s_B$, and all non-diagonal entries to vanish. However, due to weak interactions the flavour eigenstate $B^0_s$ can transform into its anti-particle $\bar{B}^0_s$ and vice versa. This transition is governed by the so-called box-diagrams, depicted in Fig. 1, and it gives rise to the off-diagonal elements $\Gamma^{s\bar{s}}$ and $\Gamma^{\bar{s}s}$ in $\Gamma^s$. Calculating these box diagrams one gets a contribution from virtual internal particles, denoted by $M^{\pm}_{12}$, and a contribution from internal on-shell particles, denoted by $\Gamma^{\pm}_{12}$. Only internal charm and up quarks can contribute to the latter, while $M^{\pm}_{12}$ is sensitive to all possible internal particles, and, in principle, also to heavy new physics particles. Due to the CKM-structure both $M^{s\bar{s}}_{12}$ and $\Gamma^{s\bar{s}}_{12}$ can be complex.

$$M^{s\bar{s}}_{12} = |M^{s\bar{s}}_{12}| e^{i \phi_{s\bar{s}}},$$

$$\Gamma^{s\bar{s}}_{12} = |\Gamma^{s\bar{s}}_{12}| e^{i \phi_{s\bar{s}}}.$$

The CKM phases $\phi_M$ and $\phi_T$ are not physical, but depend on the phase convention used in the CKM matrix. Later on we will see that

$$e^{i \phi_{s\bar{s}}} = \frac{V_{ts} V_{tb}^*}{V_{ts} V_{tb}},$$

while there is no such simple relation for $\phi_{s\bar{s}}$, because $\Gamma^{s\bar{s}}_{12}$ depends in the Standard Model on three different CKM structures.

In order to obtain the physical eigenstates of the mesons with a definite mass and decay rate, the matrices $M^s$ and $\Gamma^s$ have to be diagonalised. This gives the meson eigenstates $|B_H\rangle$ (H=heavy) and $|B_L\rangle$ (L=light) as linear combinations of the flavour eigenstates:

$$|B_L\rangle = |B^0_s\rangle + q |\bar{B}^0_s\rangle,$$

$$|B_H\rangle = |B^0_s\rangle + q |\bar{B}^0_s\rangle,$$

which are in general not orthogonal. The complex coefficients $p$ and $q$ fulfill $|p|^2 + |q|^2 = 1$ and the corresponding masses and decay rates of these states are denoted by $M^s_{H}$, $M^s_{H}$ and $\Gamma^s_{L}$, $\Gamma^s_{H}$. The mass eigenstates of the $B^0_s$ mesons are almost CP eigenstates. Using the same conventions as e.g. [Dunietz et al. 2001] for the CP properties and defining

$$CP |B^0_s\rangle = - |\bar{B}^0_s\rangle,$$

we get for the CP eigenstates of the $B^0_s$ meson

$$|B^0_{s,\text{even}}\rangle = \frac{1}{\sqrt{2}} \left( |B^0_s\rangle - |\bar{B}^0_s\rangle \right),$$

$$|B^0_{s,\text{odd}}\rangle = \frac{1}{\sqrt{2}} \left( |B^0_s\rangle + |\bar{B}^0_s\rangle \right).$$

In the absence of CP violation in mixing, which will turn out to be a small effect, the heavy eigenstate is CP-odd ($|B_H\rangle \approx |B^0_{s,\text{odd}}\rangle$) and the light one is CP-even ($|B_L\rangle \approx |B^0_{s,\text{even}}\rangle$) - in that case one has $p = 1/\sqrt{2}$ and $q = -1/\sqrt{2}$.

Coming back to the diagonalisation problem and expanding[2] the eigenvalues of $M^s$ and $\Gamma^s$ in powers of $|\Gamma^s_{12}/M^s_{12}| \approx 5 \times 10^{-3}$ in the SM, one can express the mass and decay rate differences as

$$\Delta M_s := M^s_{H} - M^s_{L} = 2 |M^s_{12}| \left( 1 - \frac{|\Gamma^s_{12}|^2 \sin^2 \phi_{s\bar{s}}^{12}}{8 |M^s_{12}|^2} + ... \right),$$

$$\Delta \Gamma_s := \Gamma^s_{L} - \Gamma^s_{H} = 2 |\Gamma^s_{12}| \cos \phi_{s\bar{s}}^{12} \left( 1 + \frac{|\Gamma^s_{12}|^2 \sin^2 \phi_{s\bar{s}}^{12}}{8 |M^s_{12}|^2} + ... \right)$$

with the mixing phase

$$\phi_{s\bar{s}}^{12} := \text{arg} \left( \frac{-M^s_{12}}{\Gamma^s_{12}} \right) = \pi + \phi_M - \phi_T.$$

In contrast to $\phi_M$ and $\phi_T$, this phase difference is physical. We follow here the definition given in [Aaij et al. 2013b]. In e.g. [Ameekev et al. 2001] [Lenz and Nierste 2007] $\phi_{s\bar{s}}^{12}$ is denoted as $\phi_s$. However, in the literature the notation $\phi_s$ is often used for different quantities, also related to CP violation in interference. We will define the phase that appears in interference in Section IV.

The correction factor $1/8 |\Gamma^s_{12}/M^s_{12}|^2 \sin^2 \phi_{s\bar{s}}^{12}$ in Eq.(11)

---

1 There can also be new physics contributions to $\Gamma^{s\bar{s}}_{12}$, e.g. by modified tree-level operators or by new $bs\tau\tau$-operators, as discussed below.

2 Such an expansion does not hold in the charm system, because there $\Delta \Gamma$ and $\Delta M$ are of a similar size.
and Eq. (12) is of the order of $6 \cdot 10^{-11}$ in the Standard Model and the current experimental bound for this factor is smaller than $5 \cdot 10^{-5}$, thus it can be safely neglected. Diagonalisation of $M^s$ and $\tilde{Γ}^s$ gives also

$$ q/p = -e^{-iφ_M} \left[ 1 - \frac{1}{2} \frac{Γ^s_{12}}{M^s_{12}} \sin φ^s_{12} + \mathcal{O} \left( \frac{Γ^s_{12}^2}{M^s_{12}^2} \right) \right] $$

$$ = -\frac{V_{ts}V^*_{tb}}{V^*_{ts}V_{tb}} \left[ 1 - \frac{a^s_{12}}{2} \right] + \mathcal{O} \left( \frac{Γ^s_{12}^2}{M^s_{12}^2} \right), \quad (14) $$

with the abbreviation

$$ a^s_{12} = \frac{Γ^s_{12}}{M^s_{12}} \sin φ^s_{12}. \quad (15) $$

Later on, in Section III, we will see that $a^s_{12}$ equals the so-called flavour-specific CP asymmetry. From Eq. (14) it follows also that, in the absence of CP-violation in mixing, $q/p = -1$. In Eq. (14) again all terms of order $|Γ^s_{12}|^2/|M^s_{12}|^2$ can be discarded, many times also the term of order $a^s_{12}$ is not necessary.

We can now write down the time evolution of the flavour eigenstates of the $B^0_s$ meson$^3$ $|B^0_s(t)\rangle$ denotes a meson at time $t$ that was produced as a $B^0_s$ meson at time $t = 0$. At a later time $t$, $|B^0_s(t)\rangle$ will have components both of $|B^0_s\rangle$ and $|B^0_{s^c}\rangle$:

$$ |B^0_s(t)\rangle = g_+(t)|B^0_s\rangle + \frac{q}{p} g_-(t)|B^0_{s^c}\rangle, \quad (16) $$

$$ |B^0_{s^c}(t)\rangle = \frac{p}{q} g_+(t)|B^0_s\rangle + g_-(t)|B^0_{s^c}\rangle, \quad (17) $$

with the coefficients

$$ g_+(t) = e^{-iM_{s^c}t}e^{-\frac{1}{2}Γ_{s^c}t}, \quad (18) $$

$$ g_-(t) = e^{-iM_s t}e^{-\frac{1}{2}Γ_s t}. \quad (19) $$

Here we used the averaged mass $M_{B^0_s}$ and decay rate $Γ_s$:

$$ M_{B^0_s} = \frac{M_H + M_{s^c}}{2}, \quad Γ_s = \frac{Γ_H + Γ_{s^c}}{2}. \quad (20) $$

Next we also can write down the time evolution of the decay rate for an $B^0_s$ meson, that was initially (at time $t = 0$) tagged as a $B^0_s$ flavour eigenstate into an arbitrary final state $f$.

$$ Γ \left[ B^0_s(t) \rightarrow f \right] = N_f |A_f|^2 \left( 1 + |λ_f|^2 \right) e^{-Γ_s t} \left\{ \frac{\cosh (\frac{Δ_T}{2} t) + 1 - |λ_f|^2 \cos (ΔM_s t)}{2 \left( 1 + |λ_f|^2 \right)} \right. $$

$$ - \frac{2ℜ(λ_f)}{1 + |λ_f|^2} \frac{\sinh (\frac{Δ_T}{2} t)}{2} - \frac{23(λ_f)}{1 + |λ_f|^2} \frac{\sin (ΔM_s t)}{2} \right\}. \quad (21) $$

Here $N_f$ denotes a time-independent normalisation factor, which includes e.g. phase space effects. The decay amplitude describing the transition of the flavour eigenstate $B^0_s$ in the final state $f$ is denoted by $A_f$; for the decay of a $B^0_s$ state into $f$ we use the notation $A_f$:

$$ A_f = \langle f | H_{eff} | B^0_s \rangle, \quad \bar{A}_f = \langle f | H_{eff} \rangle | B^0_s \rangle. \quad (22) $$

The flavour changing weak quark transitions are described by an effective Hamiltonian including also perturbative and non-perturbative QCD-effects. $H_{eff}$ will

---

$^3$ A more detailed discussion of the $B^0_s$ mixing system and its time evolution can be found in e.g. [Anikeev et al.], 2001.
be described in more detail in Section [V, A] The amplitudes $A_f$ and $\bar{A}_f$ are typically governed by hadronic effects and they are very difficult to be calculated reliably in theory. In Section [V, A] it will also be shown that CP-symmetries are governed by a single quantity $\lambda_f$, which is given by

$$\lambda_f = \frac{q}{p} \frac{A_f}{\bar{A}_f} \approx -\frac{V_{tb}^* V_{ts}}{V_{ts}^* V_{tb}} \frac{A_f}{\bar{A}_f} \left[ 1 - \frac{a_t^2}{2} \right].$$

For the terms appearing on the right-hand-side of Eq. (21) the following abbreviations are typically used:

$$A_{\text{CP}}^{\text{dir}} = \frac{1 - |\lambda_f|^2}{1 + |\lambda_f|^2},$$

$$A_{\text{CP}}^{\text{mix}} = \frac{-2\tilde{\lambda}(\lambda_f)}{1 + |\lambda_f|^2},$$

$$A_{\Delta\Gamma} = -\frac{2 \Re(\lambda_f)}{1 + |\lambda_f|^2}.$$

$A_{\text{CP}}^{\text{dir}}$ describes effects related to direct CP violation, which is described in Section [V, A] This can be seen by neglecting CP violation in mixing, i.e. assuming $|q/p| = 1$ and considering the decay into a final state $f$, that is a CP eigenstate, i.e. $f = \eta_{\text{CP}} f$. With these assumptions we get $|\lambda_f| = |A_f|/|\bar{A}_f|$. A non-vanishing value for $A_{\text{CP}}^{\text{mix}}$ is obtained for $|\lambda_f| \neq 1$ and this corresponds now to $|\lambda_f| = |A_f|$, which is equivalent to direct CP violation. $A_{\text{CP}}^{\text{mix}}$ encodes effects due to interference between mixing and decay, which is discussed in Section [III] and $A_{\Delta\Gamma}$ is a kind of correction factor, due to a finite value of the decay rate difference $\Delta\Gamma_f$. $A_{\Delta\Gamma}$ also appears in the definition of the effective lifetimes $\tau_{\text{eff}}$:

$$\tau_{\text{eff}} = \frac{1}{1 - y_f^2} \left( \frac{1 + 2 A_{\Delta\Gamma} y_f + y_f^2}{1 + A_{\Delta\Gamma} y_f} \right)$$

with

$$\tau_{B^0} = \frac{1}{\Gamma_{B^0}} \quad y_f = \frac{\Delta\Gamma_f}{2\Gamma_{B^0}}.$$

$\Gamma \left[ B^0(t) \to f \right] = N_f |A_f|^2 (1 + |\lambda_f|^2) (1 + a_t^2) e^{-\Gamma t}$

$$\left\{ \frac{\cosh \left( \frac{\Delta\Gamma_f}{2} t \right)}{2} - \frac{1 - |\lambda_f|^2 \cos(\Delta M_f t)}{2} \left[ 2 \Re(\lambda_f) \frac{\sinh \left( \frac{\Delta\Gamma_f}{2} t \right)}{1 + |\lambda_f|^2} + \frac{2 \Im(\lambda_f) \sin(\Delta M_f t)}{1 + |\lambda_f|^2} \right] \right\}. \quad (33)$$

The common pre-factors, i.e. $N_f$ and $|A_f|^2 (1 + |\lambda_f|^2)$, typically cancel in CP asymmetries and we do not need to know their value. This is very advantageous because the hadronic quantity $A_f$ is notoriously difficult to calculate. For the remaining unknown parameter $\lambda_f$ in some cases additional assumptions can be made, e.g. that penguin effects are small, which enables a theory prediction for $\lambda_f$ and thus an extraction of meaningful physical results (i.e. a combination of CKM elements) from the measurement of a CP asymmetry.

For completeness we also consider the decay of $B^0$ and $\bar{B}^0$ mesons into the CP conjugate of $f$, which will be
denoted by $\bar{f}$.

$$|\bar{f}| = CP|f|.$$  

(34)

$$\Gamma [B_s^0(t) \to \bar{f}] = N_f |\bar{A}_f|^2 (1 + |\lambda_f|^2)^2 (1 - a^s_{\bar{f}}) e^{-\Gamma t} \left\{ \cosh \left( \frac{\Delta \Gamma_f}{2} t \right) - \frac{1 - |\lambda_f|^2}{1 + |\lambda_f|^2} \left( \frac{2\sinh \left( \frac{\Delta \Gamma_f}{2} t \right)}{1 + |\lambda_f|^2} + \frac{2\sin \left( \frac{\Delta \Gamma_f}{2} t \right)}{1 + |\lambda_f|^2} \right) \right\}.$$  

The above formulae can be used to extract the observables $\Delta M_s$, $\Delta \Gamma_s$, and $a^s_{\bar{f}}$ from experiment, which can then be compared with the theory predictions. According to Eqs. (11) and Eq. (12), these three observables are related to the matrix elements $\Gamma_{12}$ and $M^s_{12}$, thus a Standard Model calculation of the three mixing observables requires a calculation of the box-diagrams in Fig. 1. The calculation of the Standard Model value for $M^s_{12}$ is straightforward. In principle there are nine different combinations of internal quarks, thus we get

$$M^s_{12} \propto \lambda_2 \left[ F(u, u) + \lambda_u \lambda_c F(u, c) + \lambda_u \lambda_t F(u, t) + \lambda_c \lambda_u F(c, u) + \lambda_c \lambda_F(c, c) + \lambda_c \lambda_F(c, t) + \lambda_t \lambda_u F(t, u) + \lambda_t \lambda_c F(t, c) + \lambda_t \lambda_t F(t, t) \right]$$  

(38)

with the CKM structures $\lambda_q = V_{q\bar{s}}^\ast V_{q\bar{b}}$. The functions $F(x, y)$ depend on the masses of the quarks $x$ and $y$ normalised to the $W$ boson mass. Using CKM unitarity, i.e. $\lambda_u + \lambda_c + \lambda_t = 0$, we get

$$M^s_{12} \propto \lambda_2^2 \left[ F(c, c) - 2F(u, c) + F(u, u) \right] + 2\lambda_c \lambda_t \left[ F(c, t) - F(u, t) - F(u, c) + F(u, u) \right] + \lambda_t^2 \left[ F(t, t) - 2F(u, t) + F(u, u) \right]$$  

(39)

From this equation one sees clearly the arising GIM cancellation (Glashow et al. 1970) in all three terms: if all masses would be equal, each of the three terms would vanish. Because of that also any constant term in the functions $F(x, y)$ cancels in $M^s_{12}$ and only the mass dependent terms will survive. An explicit calculation shows that $F(x, y)$ grows strongly with the masses, thus there is a very severe GIM cancellation in the first two terms $(m_u/M_W$ and $m_c/M_W$ can be very well be approximated by zero), while the third term will give a sizable contribution $(m_t/M_W > 1)$. Since the CKM structures have all a similar size $(\lambda_c \propto \lambda^2 \propto \lambda_t$, with the Wolfenstein parameter $\lambda$ (Wolfenstein 1983)) we get to a very good approximation

$$M^s_{12} \propto \lambda_2^2 \left[ F(t, t) - 2F(u, t) + F(u, u) \right] \propto \lambda_2^2 S_0 \left( \frac{m_t^2}{M_W^2} \right)$$  

(40)

(41)

where $S_0$ denotes the Inami-Lim function (Inami and Lim 1981). In that respect it is sometimes stated that only the top quark contributes to $M^s_{12}$. Formally the process of calculating $M^s_{12}$ can be viewed as performing an operator product expansion (OPE) by integrating out the heavy $W$ boson and the heavy top quark. Since both of these masses are far above the hadronic scale and the $b$ quark mass, there is no doubt in the applicability of the OPE. This will change in the discussion of $\Gamma_{12}$. The complete calculation of $M^s_{12}$ yields

$$M^s_{12} = \frac{G_F^2}{12\pi^2} \lambda_2^2 M_W^2 S_0(x_t) B f_B^2 M_{B^0} \eta_B ,$$  

(42)

with simple pre-factors: the Fermi-constant $G_F$, the masses of the $W$-boson, $M_W$, and of the $B_s$ meson, $M_{B^0}$ and the normalisation factor $1/12\pi^2$. As we have seen above there is only one CKM structure contributing $\lambda_t := V_{ts}^\ast V_{tb}$. The CKM elements are the only place in Eq. (12) where an imaginary part can arise. By writing

$$\lambda_t^2 = |\lambda_t|^2 \frac{\lambda_t}{\lambda_t} = |\lambda_t|^2 e^{i\phi_M}$$  

(43)

we get an explicit expression for the phase $\phi_M$. As discussed above, the result of the 1-loop diagrams
given in Fig.\ref{fig:SM} is denoted by the Inami-Lim function \( S_0(x) = \langle \bar{m}_d(m_\ell) \rangle / M_B^2 \), where \( \bar{m}_d(m_\ell) \) is the MS-mass ([Bardeen et al. 1978]) of the top-quark. Perturbative 2-loop QCD corrections are compressed in the factor \( \hat{n}_B \approx 0.84 \), they have been calculated by ([Buras et al. 1990]). All hadronic effects that describe the binding of the quarks into meson states as well as the non-perturbative QCD effects contributing to the transition of the \( B_s^0 \) meson into the \( B_s^0 \) meson and vice versa are encoded in the hadronic matrix element of the arising four-quark \( \Delta B = 2 \) operator
\[
Q = s^\alpha \gamma_\mu (1-\gamma_5) b^\alpha \times s^\beta \gamma_\mu (1-\gamma_5) b^\beta . \tag{44}
\]
\( \alpha \) and \( \beta \) are the colour indices of the \( b \)- and \( s \)-quark spinors. The hadronic matrix element of this operator is parametrised in terms of a decay constant \( f_{B_s} \) and a bag parameter \( B \):
\[
\langle Q \rangle \equiv \langle B_s | Q | B_s \rangle = \frac{8}{3} \frac{s}{m_s} f_{B_s} B (\mu/m) , \tag{45}
\]
The factor \( 8/3 = 2(1+1/N_c) \) stems from the colour structure. It ensures that the bag parameter \( B \) obtains the value 1 in vacuum insertion approximation. We also indicated the renormalisation scale dependence of the bag parameter; in our analysis we take \( \mu = m_s \).

Sometimes a different notation for the QCD-corrections and the bag parameter is used in the literature (e.g. by the Flavour Lattice Averaging Group (FLAG): [Aoki et al. 2014], \( \hat{n}_B, \hat{B} \)) instead of \( (\hat{n}_B, B) \) with
\[
\hat{n}_B = : \eta_B \hat{B} \tag{46}
\]
\[
\hat{B} = 1.51599 B . \tag{47}
\]
The parameter \( \hat{B} \) has the advantage of being renormalisation scale and scheme independent.

A commonly used Standard Model prediction of \( \Delta M_s \) was given by ([Lenz and Nierste 2011])
\[
\Delta M_s^{\text{SM,2011}} = (17.3 \pm 2.6) \text{ ps}^{-1} . \tag{49}
\]
Using the most recent numerical inputs \( (G_F, M_W, M_B, \text{ and } m_b) \) from the Particle Data Group (PDG) ([Olive et al. 2014]), the top quark mass from (ATLAS and Collaborations, 2014), the non-perturbative parameters from FLAG (web-update of [Aoki et al. 2014]) and CKM elements from the CKFit group (web-update of [Charles et al. 2005]) - similar values can be taken from the UTfit group ([Bona et al. 2006b]) - we predict the mass difference of the neutral \( B_s^0 \) mesons to be
\[
\Delta M_s^{\text{SM,2015}} = (18.3 \pm 2.7) \text{ ps}^{-1} . \tag{50}
\]

---

4 Throughout this review we will use the conventional relativistic normalisation for the \( B_s^0 \) meson states, i.e. \( \langle B_s^0 | B_s^0 \rangle = 2E \) (\( E \): energy, \( V \): volume).

---

5 This value is derived from the FLAG value of \( f_{B_s} \sqrt{B} \). It is by accident equal to the value of \( f_{B_s} \sqrt{B} \) quoted from HFAG.
whether $\Lambda$ while for a transition like $b \rightarrow c \bar{c}s$. This issue has now been resolved, by both improved measurements and improved theory predictions (see [Krimmer et al. 2013]), leading to a nice agreement between experiment and theory.

- For a long time the $\Lambda_b$ lifetime was measured to be considerably shorter than theoretically (i.e. according to estimates of the HQE) expected, this issue has been resolved experimentally, mostly by the LHCb Collaboration (e.g. [Aaij et al. 2013, 2014]) but also by the Tevatron experiments (e.g. [Altonen et al. 2014]). The history of the $\Lambda_b$-lifetime puzzle - HFAG quoted 2003 a value of $\tau_{\Lambda_b} = (1.229 \pm 0.080)$ ps, which is about 3 standard deviations away from the 2015 average of $\tau_{\Lambda_b} = (1.466 \pm 0.010)$ ps - and also (sometimes embarrassing) theoretical attempts to obtain low theory values are discussed in detail in the review of [Lenz 2014]. From a modern point of view, one finds that the old, low experimental values are mostly triggered by the use of semi-leptonic decays with an undetectable neutrino (Stone 2014), while new measurements use non-leptonic decays. The huge range in the theory predictions for the $\Lambda_b$ lifetime stems from our missing knowledge about the size of the hadronic matrix elements. Some theory groups tried to create some extraordinary large enhancements of these matrix elements in order to describe the experimental data, while other groups - including e.g. Bigi and Uraltsev, stuck to theory estimates that were in conflict with the old measurements, but agree perfectly with the new ones. The current status of lifetimes is depicted in Fig. 3. One finds a nice agreement between experiment and theory and no lifetime puzzle exists anymore. The theoretical precision is, however, strongly limited by a lack of up-to-date values for the arising non-perturbative parameters. For the $\Lambda_b$-baryon the most recent lattice numbers stem from 1999 ([Di Pierro et al. 1999]) and for the $B$ mesons the most recent numbers are from 2001 ([Becirevic 2001]). This lack of theoretical investigations limits also our current knowledge about the intrinsic precision of the HQE.

- Since $\Delta\Gamma_s$ is dominated by a $b \rightarrow c \bar{c}s$ transition, the applicability of the HQE was in particular questioned for $\Delta\Gamma_s$, see e.g. [Ligeti et al. 2010] and the discussion in [Lenz 2011] and the references therein. In the last years this was also related to the unexpected measurement of a large value of the dimuon asymmetry by the D0 collaboration ([Abazov et al. 2010a, b, 2011, 2014]). In 2012 the issue of
The general structure of the leading term $\Gamma_3^s$ has three $(uc = cu)$ different CKM contributions

$$\Gamma_3^s = - \sum_{x=u,c} \sum_{y=\bar{u},\bar{c}} \lambda_x \lambda_y \bar{y}_x^s \langle Q \rangle$$

and each factor $\Gamma_{12}^{s,xy}$ has contributions of the three operators $Q$, $Q_S$ and $Q_S$

$$\Gamma_{12}^{s,xy} = \Gamma_{xy}^s (Q) + \Gamma_{xy}^{s,Q_S} (Q_S) + \Gamma_{xy}^{s,\bar{Q}_S} (\bar{Q}_S).$$

The matrix elements of the new operators are typically parameterised as

$$\langle Q_S \rangle \equiv \langle \bar{B}_s | Q_S | B_s \rangle = -\frac{5}{3} M_{B_s}^2 f_{B_s}^2 B'_S,$$  

$$\langle \bar{Q}_S \rangle \equiv \langle \bar{B}_s | Q_S | B_s \rangle = \frac{1}{3} M_{B_s}^2 f_{B_s}^2 B'_S,$$

with the modified bag parameters

$$B'_X = \frac{M_{B_s}^2}{m_b (m_b + \tilde{m}_s (\tilde{m}_b))} B_X \approx 1.57706 B_X.$$  

In vacuum insertion approximation the unmodified bag parameters are equal to one. More reliable values can be obtained by using non-perturbative methods like QCD sum rules or lattice QCD. $Q$, $Q_S$ and $Q_S$ were determined by several lattice groups, who actually determined all five operators of the so-called SUSY basis\footnote{A QCD sum rule determination of $\langle Q \rangle$ is given e.g. in \cite{Korner et al. 2003}. We will, however, not use the number obtained there in our analysis.} (\cite{Becirevic et al. 2002}, (\cite{Carrasco et al. 2014} and (\cite{Dowdall et al. 2014}) use the notation $O_1$, $O_2$ and $O_3$ for these three operators:

$$Q \equiv O_1 , Q_S \equiv O_2 , \tilde{Q}_S \equiv O_3.$$  

In the case of (\cite{Bouchard et al. 2011} there is also an additional factor 4 present.

$$Q \equiv 4O_1 , Q_S \equiv 4O_2 , \tilde{Q}_S \equiv 4O_3.$$  

\cite{Becirevic et al. 2002} and \cite{Carrasco et al. 2014} use the same definitions of the bag parameters as we do

$$B \equiv B_1 , B_s \equiv B_2 , \tilde{B}_s \equiv B_3.$$  

while \cite{Dowdall et al. 2014} and \cite{Bouchard et al. 2011} use the modified bag parameters

$$B \equiv B_1 , B'_s \equiv B_2 , \tilde{B}'_s \equiv B_3.$$  

$\Delta \Gamma_s$ was solved experimentally by a direct measurement of this quantity by the LHCb Collaboration. The current HFAG (\cite{Amhis et al. 2014}) average, combining values from LHCb, ATLAS, CMS, D0 and CDF, is in perfect agreement with the HQE prediction from (\cite{Lenz and Nierste 2011}), which is based on on the calculations of (\cite{Beneke et al. 1999a, 2003, Ciuchini et al. 2003, Lenz and Nierste 2007}. This will be discussed in detail below.

All in all the HQE has been experimentally proven to be very successful and one could try next to test its applicability also for charm-physics, see e.g. (\cite{Bobrowski et al. 2010, Lenz and Rauh 2013} for some recent investigations. Charm studies would be very helpful for studying the intrinsic uncertainties of the HQE. Having more confidence in the validity of HQE, it can now also be applied to quantities that are sensitive to new physics, in particular the semi-leptonic CP asymmetries, which will be discussed in Section III.

According to the HQE, $\Gamma_{12}^{s}$ can be expanded as a power series in the inverse of the heavy $b$-quark mass and the strong coupling:

$$\Gamma_{12} = \frac{\Lambda^3}{m_b^3} \left( \Gamma_{3}^{s,(0)} + \frac{\alpha_s}{4\pi} \Gamma_{3}^{s,(1)} + \ldots \right) + \frac{\Lambda^4}{m_b^4} \left( \Gamma_{4}^{s,(0)} + \ldots \right) + \ldots$$

$\Lambda$ denotes a hadronic scale, which is assumed to be of the order of $\Lambda_{QCD}$, but its actual value has to be determined by a non-perturbative calculation. Each of the $\Gamma_{i}^{s,(1)}$ is a product of perturbative Wilson coefficients and non-perturbative matrix elements. In $\Gamma_3^s$ these matrix elements arise from dimension 6 four-quark operators, in $\Gamma_4^s$ from dimension 7 operators and so on.

The leading term in Eq. (\ref{eq:13}), $\Gamma_{3}^{s,(0)}$, was calculated already quite long ago by (\cite{Ellis et al. 1977}, (\cite{Hagelin 1981}, (\cite{Franco et al. 1982}, (\cite{Chau 1983}, (\cite{Buras et al. 1984} and (\cite{Khoze et al. 1987}). Here three different 4-quark operators arise; besides $Q$ from Eq. (\ref{eq:12}) these are

$$Q_s = s^a (1 + \gamma_5) b^\alpha \times s^b (1 + \gamma_5) b^\beta ,$$

$$Q_S = \bar{s}^a (1 + \gamma_5) b^\alpha \times \bar{s}^b (1 + \gamma_5) b^\beta .$$

Fig. 3 Comparison of HQE predictions for lifetime ratios of heavy hadrons with experimental values. The theory values are taken from (\cite{Lenz 2014}). Experimental numbers are taken from HFAG (\cite{Amhis et al. 2014}).
It turns out, that these three operators are not independent (see e.g. Beneke et al. (1996)) and that the following relation holds

$$R_0 = Q_S + \alpha_1 \tilde{Q}_S + \frac{\alpha_2}{2} Q = 0 + \mathcal{O} \left( \frac{\Lambda}{m_b} \right),$$  \hspace{1cm} (66)$$

with the coefficients (obtained in Beneke et al. (1999a) using the renormalisation scheme described there)

$$\alpha_1 = 1 + \frac{\alpha_s(\mu)}{3\pi} \left[ 12 \ln \left( \frac{\mu}{m_b} \right) + 6 \right],$$  \hspace{1cm} (67)$$

$$\alpha_2 = 1 + \frac{\alpha_s(\mu)}{3\pi} \left[ 6 \ln \left( \frac{\mu}{m_b} \right) + \frac{13}{2} \right].$$  \hspace{1cm} (68)$$

With the help of Eq. (66) one can eliminate one of the three operators; historically $\tilde{Q}_S$ was eliminated. So one gets

$$\Gamma^{{s,x_y}}_{12} = \left[ \Gamma^{{s,0}}_{x_y} - \frac{1}{2} \alpha_1 \Gamma^{{s,x_y}}_{x_y} \right] (Q) + \left[ \Gamma^{{s,0}}_{x_y} - \frac{1}{2} \alpha_1 \Gamma^{{s,x_y}}_{x_y} \right] (Q_S) + \mathcal{O} \left( \frac{\Lambda}{m_b} \right),$$  \hspace{1cm} (69)$$

which was denoted in the literature as

$$\Gamma^{{s,x_y}}_{12} = \frac{G_F^2 m_b^2}{24\pi M_{B_S}} \left[ G^{{s,x_y}}(Q) - G^{{s,x_y}}(Q_S) \right] + \Gamma^{{s,x_y}}_{12, \frac{1}{m_b}}$$  \hspace{1cm} (70)$$

$$= \frac{G_F^2 m_b^2 f_{B_S}^2 M_{B_S}^2}{24\pi} \left[ 8 G^{{x_y}}B + 5 G^{{x_y}}B_S \right] + \Gamma^{{s,x_y}}_{12, \frac{1}{m_b}},$$

where the Wilson coefficients $G^{{s,x_y}}$ and $G^{{s,x_y}}_S$ contain the result of the calculation of the box-diagrams with internal on-shell up- and/or charm quarks; $x_y \in \{uu, uc, cc\}$. Neglecting the mass of the charm quark and penguin contributions, $G^{{s,x_y}}$ and $G^{{s,x_y}}_S$ read in LO-QCD

$$G^{{s,x_y}} = 3 C_1^2 + 2 C_1 C_2 + \frac{1}{2} C_2^2,$$  \hspace{1cm} (71)$$

$$G^{{s,x_y}}_S = 3 C_1^2 + 2 C_1 C_2 - \frac{1}{2} C_2^2,$$  \hspace{1cm} (72)$$

where $C_{1,2}$ denote the usual $\Delta B = 1$-Wilson coefficients of the effective Hamiltonian describing $b$-quark decays (in our notation $C_2$ corresponds to the colour allowed operator). Early LO-QCD estimates of $G^{{s,x_y}}$ and $G^{{s,x_y}}_S$ can be found in the works of Ellis et al. (1977), Hagelin (1981), Franco et al. (1982), Chau (1983), Buras et al. (1984) and Khoze et al. (1987). NLO QCD-corrections, i.e. $\Gamma^{{s,(1)}}$ in Eq. (54), were done for the first time in Beneke et al. (1999a), they turned out to be quite large. This calculation was also a proof of the IR-safety of the HQE by direct calculation. The corresponding NLO-QCD diagrams are shown in Fig. 3. General arguments for such a proof were given already in the seminal paper of Bigi and Uraltsev (1992) which resolved the theoretical issues that were prohibiting a systematic expansion in the inverse of the heavy $b$-quark mass. Five years later the issue of the QCD-corrections was confirmed and also sub-leading CKM structures were included by Beneke et al. (2003) and Ciuchini et al. (2003). In these papers the full expressions for $G^{{s,x_y}}$ and $G^{{s,x_y}}_S$ are given; they also include contributions from the QCD penguin operators $Q_1 - Q_6$ and the chromo-magnetic penguin operator $Q_8$.

In Eq. (70) the term $\Gamma^{{s,x_y}}_{12, \frac{1}{m_b}}$ denotes sub-leading $1/m_b$ corrections to $\Gamma^{{s,x_y}}_{12}$ - in Eq. (54) these terms were called $\Gamma^{{s,(0)}}_4$. Such sub-leading $1/m_b$ corrections were first calculated by Beneke et al. (1996) and they also turned out to be quite sizable. Here the arising operators are of dimension 7 (e.g. four quark operators with one derivative). These operators are denoted by $R_0, R_1, R_2$ and $R_3$, as well as the colour-rearranged counterparts $\tilde{R}_1, \tilde{R}_2$ and $\tilde{R}_3$, see e.g. Lenz and Niess 2007 for more details. The operators $R_0, R_1$ and $\tilde{R}_1$ can be reduced to four-quark operators (see e.g. the definition of $R_0$ in Eq. (66) and thus they can be studied with current lattice technologies; their results can be deduced from Beccirevic et al. (2002), Bouchard et al. (2011), Carrasco et al. (2014) and Dowdall et al. (2014), who were calculating the full five-dimensional SUSY-basis of $\Delta B = 2$-operators. All of those five operators contribute to $\Gamma^{{s,2}}$. The genuine dimension 7 operators $R_2, R_3, \tilde{R}_2$ and $\tilde{R}_3$ are considerably more complicated. For the corresponding matrix elements currently no lattice determination is available, so we have to rely on vacuum insertion approximation, i.e. the bag parameters $B_{R_2}, B_{R_3}, B_{\tilde{R}_2}$ and $B_{\tilde{R}_3}$ are set to one. First steps towards a non-perturbative determination of these matrix elements within the framework of QCD sum rules have been done by Mannel et al. 2007, 2011. Here a more complete study would be very desirable, because - as will be seen below - these parameters give currently the dominant uncertainty to $\Gamma^{{s,2}}$.

At this stage now several comments are in order:

- $\Gamma^{{s,2}}_{12}$ depends on $f_{B_S} B$, which is currently not very well-known. Thus, it might be advantageous to consider the ratio $\Gamma^{{s,2}}_{12}/M^{{s,2}}_{12}$, where the decay constant cancels. One gets from this ratio

$$\text{Re} \left( \frac{\Gamma^{{s,2}}}{M^{{s,2}}_{12}} \right) = - \frac{\Delta \Gamma^{{s,2}}}{\Delta M^{{s,2}}}.$$  \hspace{1cm} (74)$$

The ratio $\Gamma^{{s,2}}_{12}/M^{{s,2}}_{12}$ can be further modified by using...
the CKM unitarity ($\lambda_u + \lambda_c + \lambda_t = 0$):

$$- \frac{\Gamma_{12}^{s}}{M_{12}^{s}} = \frac{\lambda_c^2 \Gamma_{12}^{cc} + 2 \lambda_c \lambda_u \Gamma_{12}^{uc} + \lambda_t^2 \Gamma_{12}^{uu}}{\lambda_t^2 M_{12}^{t}} + \left( \frac{\lambda_u}{\lambda_t} \right)^2 \Gamma_{12}^{uc} - \Gamma_{12}^{uc}$$

$$= -10^{-4} \left[ c + a \frac{\lambda_u}{\lambda_t} + b \left( \frac{\lambda_u}{\lambda_t} \right)^2 \right] , \quad (77)$$

where $\tilde{M}_{12}^t$ is defined in such a way that only the CKM-dependence of $M_{12}^t$ in Eq. (77) is split off. Eq. (77) introduces the $a$, $b$ and $c$ notation of (Beneke et al. 2003). In the ratios $\Gamma^{s,xy}_{12}/\tilde{M}_{12}^s$ - which are the building blocks of the parameters $a$, $b$ and $c$ - many quantities cancel, in particular the decay constant $f_B$, the mass of the $B_s$ meson and the Fermi constant. We get

$$\frac{\Gamma^{s,xy}_{12}}{\tilde{M}_{12}^s} = \frac{\pi m_B^2}{6 M_W S_0(x_f) \eta_B} \left[ 8 G^{s,xy} + 5 G^{s,xy} \frac{B_s^0}{B} + O \left( \frac{1}{m_{\pi}} \right) \right] . \quad (78)$$

Now the first term, proportional to $G^{s,xy}$ is completely free of any non-perturbative contribution.

It can be completely determined in perturbative QCD. Because of all these cancellations $a$, $b$ and $c$ are theoretically quite clean and they are also almost identical for $B_d$ and $B_s$ mesons, except for differences in the primed bag factors and in the $1/m_b$ corrections. The way of writing $\Gamma^{s}_{12}/\tilde{M}_{12}^s$ in Eq. (76) and Eq. (77) can be viewed as a Taylor expansion in the small CKM parameter $\lambda_u/\lambda_t$, for which we get

$$\frac{\lambda_u}{\lambda_t} = -8.0486 \cdot 10^{-3} + 1.81082 \cdot 10^{-2} I , \quad (79)$$

$$\left( \frac{\lambda_u}{\lambda_t} \right)^2 = -2.63126 \cdot 10^{-4} - 2.91491 \cdot 10^{-4} I . \quad (80)$$

Moreover a pronounced GIM (Glashow et al. 1970) cancellation is arising in the coefficients $a$ and $b$ in Eq. (77). With the newest input parameters described in the appendix we get for the numerical values of $a$, $b$ and $c$:

$$c = -48.0 \pm 8.3 \quad (-49.5 \pm 8.5) , \quad (81)$$

$$a = +12.3 \pm 1.4 \quad (+11.7 \pm 1.3) , \quad (82)$$

$$b = +0.79 \pm 0.12 \quad (+0.24 \pm 0.06) . \quad (83)$$

The numbers in brackets denote the corresponding values for the $B^0$ system. Putting all this together,
we see that the real part of $\Gamma_{12}^s/M_{12}$ is absolutely dominated by the coefficient c, while for the imaginary party only a and to a lesser extent b are contributing. We get

$$R\left(\frac{\Gamma_{12}^s}{M_{12}}\right) = 10^{-4} \left( c + a R \left[ \frac{\lambda_u}{\lambda_t} \right] + b R \left[ \frac{\lambda_u^2}{\lambda_t^2} \right] \right)$$

$$\Rightarrow \frac{\Delta \Gamma_s}{\Delta M_s} \approx -10^{-4} c , \quad (84)$$

$$\Im\left(\frac{\Gamma_{12}^s}{M_{12}}\right) = 10^{-4} \left( a \Im \left[ \frac{\lambda_u}{\lambda_t} \right] + b \Im \left[ \frac{\lambda_u^2}{\lambda_t^2} \right] \right)$$

$$\Rightarrow a_{fs} \approx 10^{-4} a \Im \left[ \frac{\lambda_u}{\lambda_t} \right] . \quad (85)$$

So for a determination of only $\Delta \Gamma_s$ (or also $\Delta \Gamma_d$) to a good approximation the first term of Eq.(76) - or equivalently the coefficient c - is sufficient.

- Unfortunately it turned out after the calculation of the NLO-QCD and the sub-leading $1/m_b$ corrections that $\Delta \Gamma_s$ is not very well-behaved (see (Lenz 2004)): all corrections are quite large and they have the same sign. Surprisingly this problem could be solved to a large extent by using Q and $Q_S$ as the two independent operators instead of Q and $Q_S$, which is just a change of the operator basis, see (Lenz and Nierste 2007). As an illustration of the improvement we discuss the real part of the ratio $\Gamma_{12}^s/M_{12}$ and split up the terms according to Eq.(78). We leave only the ratio of bag parameter as free parameters, while we else insert all Standard Model parameters according to the values given in the appendix. We get now for $\Delta \Gamma_s/\Delta M_s$ in the old (operators Q and $Q_S$) and the new basis (operators Q and $Q_S$):

$$\Delta \Gamma_s \over \Delta M_s \quad \text{Old} \quad = 10^{-4} \left[ 2.6 + 69.7 {B_S \over B} - 24.3 {B_R \over B} \right] , \quad (86)$$

$$\Delta \Gamma_s \over \Delta M_s \quad \text{New} \quad = 10^{-4} \left[ 44.8 + 16.4 {\bar{B}_S \over B} - 13.0 {\bar{B}_R \over B} \right] . \quad (87)$$

where $B_R$ is an abbreviation for all seven bag parameters of the dimension 7 operators. In the old basis the first term, which has no dependence on non-perturbative lattice parameters, is almost negligible. The second term, that depends on the ratio of the matrix elements of the operators $Q_S$ and Q is by far dominant and the third term, that describes $1/m_b$-corrections gives an important negative contribution. Now, in the new basis the first term, being completely free of any non-perturbative uncertainties, is numerical dominant. The second term is sub-dominant and the $1/m_b$-corrections became smaller and undesired cancellations therein are less pronounced. Thus the second formulation has a much weaker dependence on the badly known bag parameters, also on the dimension seven ones. If all bag parameters would be known precisely, then such a change of basis has of course no effect, but since $B_R$ is unknown and the ratios $B_S/\bar{B}$ and $B_R/\bar{B}$ are much worse known compared to $B/B = 1$, now a basis, where the coefficients of $B_R/B$ and $B_S/\bar{B}$ are small, gives results with a much better theoretical control. For more details we refer the reader to (Lenz and Nierste 2007).

Currently also $1/m_b$-corrections for the sub-leading CKM structures in $\Gamma_{12}^s$ (((Dighe et al. 2002) and $1/m_b^2$-corrections for $\Delta \Gamma_s$ ((Badin et al. 2007)) are available - they are relatively small.

A commonly used Standard Model prediction for $\Delta \Gamma_s$ was given by (Lenz and Nierste 2011)

$$\Delta \Gamma_{s,SM,2011} = (0.087 \pm 0.021) \text{ ps}^{-1} \quad . \quad (88)$$

With the most recent numerical inputs ($G_F$, $M_W$, $M_{B_s}$ and $m_b$ from the PDG ((Olive et al. 2014)), the top quark mass from (ATLAS and Collaborations 2014), the non-perturbative parameters from FLAG (web-update of (Aoki et al. 2014)) and $B_S/B$, $B_{R_s}$, $B_{R_t}$ and $B_R$ from (Becirevic et al. 2002), (Bouchard et al. 2011), (Carrazzo et al. 2014) and (Dowdall et al. 2014) and CKM elements from CKMfitter (web-update of (Charles et al. 2005)) [similar values can be taken from UTfit ((Bona et al. 2006b))], we predict the decay rate difference of the neutral $B_s$ mesons to be

$$\Delta \Gamma_{s,SM,2015} = (0.088 \pm 0.020) \text{ ps}^{-1} \quad . \quad (89)$$

The dominant uncertainty stems now from the dimension 7 bag parameter $B_{R_2}$ (about 15%), briefly followed by $f_{B_s}\sqrt{B}$ (about 14 %) and the renormalisation scale dependence, which contributes about 8% to the error budget. A detailed listing of all the contributing uncertainties can be found in the appendix. In order to reduce the theory uncertainty to a value between 5% and 10% , a non-perturbative determination of $B_{R_2}$, a calculation of NNLO-QCD corrections (denoted by $\Gamma_{4}^{s(2)}$ in Eq.(54) , a first step in this direction, has been done by (Ashtarian et al. 2012) and by $\Gamma_{4}^{s(1)}$) and more precise values of the matrix elements of the operators $Q$, $Q_S$ and $Q_S$ are mandatory. All of this seems to be feasible in the next few years.

In the discussion of the di-muon asymmetry below we will also need several mixing quantities from the $B^0$-sector. Their calculation within the Standard Model is analogous to the one in the $B^0$-sector. We present here numerical updates of the predictions given in (Lenz and Nierste 2011). The input parameters are identical to the ones in the $B^0$ system, except $f_{B_s}\sqrt{B}$, $B_S/B$, $M_{B_S}$ and $m_d$, which can found in the same literature as the values
for the $B_s^0$ system. Our new predictions are

$$
\Delta M_{s,2015}^{SM} = (0.528 \pm 0.078) \text{ ps}^{-1},
$$

$$
\Delta \Gamma_{d,2015}^{SM} = (2.61 \pm 0.59) \times 10^{-3} \text{ ps}^{-1},
$$

$$
\left( \frac{\Delta \Gamma_{d,2015}^{SM}}{\Gamma_d} \right) = (3.97 \pm 0.90) \times 10^{-3},
$$

$$
\Re \left( \frac{\Gamma_{d,2015}^{SM}}{M_{12}^d} \right) = (-49.4 \pm 8.5) \times 10^{-4}.
$$

A detailed error analysis is given in the appendix.

B. Experiment: Mass and decay rate difference $\Delta M_s$ and $\Delta \Gamma_s$

Experimental studies of $\Delta M_s$ and $\Delta \Gamma_s$ and their comparison with the theoretical predictions of Eq.50 and Eq.59 constitute an important SM test. In addition, $\Delta M_s$ together with the mass difference $\Delta M_d$ of the $B^0$ meson can be used to evaluate the ratio of the CKM parameters $|V_{ts}/V_{td}|$. These elements are not likely to be measurable with high precision in tree-level decays involving a top-quark, because the top quark is too short-lived to form a hadron (see e.g. (Olive et al., 2014)), but the ratio between $\Delta M_d$ and $\Delta M_s$ provides a theoretically clean and precise constraint. Using the results discussed below, and un-quenched lattice calculations, Ref. (Olive et al., 2014) quotes

$$
|V_{td}/V_{ts}| = 0.216 \pm 0.001 \pm 0.011,
$$

where the first error stems from experiment and the second from theory. Therefore, the measurement of $\Delta M_s$, although not directly related to CP violation, contributes significantly to the test of the unitarity of the CKM matrix (Amhis et al., 2014).

The measurement of $\Delta M_s$ and $\Delta \Gamma_s$ eluded experimentalists for a very long time. A relatively large value of $|V_{ts}|$ results in a high oscillation frequency of $B_s^0$ mesons and numerous transitions from particle to anti-particle during its lifetime. Therefore, a high precision of the proper decay length measurement is required to be sensitive to $\Delta M_s$. On the other side, the measurement of $\Delta \Gamma_s$ is also challenging because of the relatively small value of $\Delta \Gamma_s/\Gamma_s$.

The measurement of $\Delta M_s$ was attempted by many experiments during more than 20 years; the CDF collaboration at Fermilab first succeeded to perform it with a statistical significance exceeding five standard deviations (Abulencia et al., 2006).

From a technical point of view, the measurement of $\Delta M_s$ requires these essential components:

- identification of the flavor of the $B_s^0$ meson at the time of production;
- identification of the flavor of the $B_s^0$ meson when it decays;
- measurement of its proper lifetime.

To measure the final state of the $B_s^0$ meson decay, a flavour-specific transition is used. The simplest flavour-specific state is the semi-leptonic decay $B_s^0 \rightarrow D_s^- \mu^+ \nu_\mu$ since the muon usually provides an excellent possibility for an efficient selection of such decays during both the data taking and the subsequent analysis. However, the precision of the proper lifetime measurement in this decay mode is rather poor because of the missing neutrino taking some part of the $B_s^0$ momentum. Figure 5 shows the proper decay time resolution for different decay modes as a function of the $B_s^0$ proper decay time in the CDF measurement. The resolution in the semi-leptonic decay channel deteriorates very quickly with the increase of the proper time. Therefore, the ability of an experiment to reconstruct hadronic $B_s^0$ decays such as $B_s^0 \rightarrow D_s^- \pi^+$ plays a crucial role in the $\Delta M_s$ measurement.

![Figure 5](image)

**FIG. 5** The proper decay time resolution measured by the CDF collaboration. The plot is taken from Ref. (Abulencia et al., 2006).

The identification of the $B_s^0$ initial state, also known as the *initial flavour tagging* (IFT), was first developed for hadron colliders by the CDF (Abulencia et al., 2006) and D0 (Abazov et al., 2006b) experiments at the Tevatron. In the LHCb implementation of the IFT (Aaltonen et al., 2012b, 2013a, 2015a), the special capabilities of the detector, such as the particle identification and efficient reconstruction of secondary decays, are extensively used.

Technically, the IFT is divided into opposite-side (OS) and same-side (SS) tagging. The OS tagging is based
on the correlation of the flavours of two produced $B$ hadrons, while the SS tagging exploits the correlation of the flavour of the $B^0$ meson and the charge of additional particles produced in the hadronisation of the initial $b$ quark. The performance of the IFT is quantified by the tagging power $P$, which is expressed as $P = \epsilon (1 - 2w)^2$, where $\epsilon$ is the tagging efficiency and $w$ is the wrong-tag probability. The tagging power multiplied by the total number of events in the analysis corresponds to the effective statistics used to measure $\Delta M_s$.

The performance of the IFT in different experiments is presented in Table I. It includes the results of the ATLAS ((Abazov et al. 2006)) and CMS ((Khachatryan 2015)) collaborations, who use the IFT for the measurement of CP violation. It can be seen that the tagging power never exceeds few percents meaning that a large statistics should be collected to obtain the significant measurement of $\Delta M_s$. In general, the tagging power improves with a better understanding of the underlying event and with the refinement of multi-variate tagging methods. Table II taken from Ref. (Koppenburg 2015) shows the improvement in tagging performance during Run I at the LHC. These progresses are likely to continue. In addition, these data show that the performance is mode-dependent.

TABLE I Performance of the initial flavour tagging in different experiments. The numbers shown correspond to the same-side (SS) or the opposite-side (OS) tagging power ($P$). In general, flavour tagging depends upon the mode being investigated. CDF finds a SS tagging power of $P = (4.8±1.2)\%$ (Abulencia et al. 2006) in the semileptonic decay sample.

The period of oscillation of the $B^0_s$ meson corresponding to $\Delta M_s = 17.76$ ps$^{-1}$ is $T = 2\pi/\Delta M_s \simeq 350$ fs. To measure it reliably and thus extract $\Delta M_s$, the precision of the proper lifetime measurement should be at least four times better. The precision of the proper decay length measurement in the CDF experiment was about 100 fs, while for the LHCb experiment it is about 44 fs. This excellent performance together with large statistics collected by the LHCb experiment in the LHC Run I results in a much better precision of the $\Delta M_s$ measurement. They also succeeded to obtain a clear oscillation pattern in the proper decay length distribution, which is shown in Fig. 6.

The first double sided bound at 90% C.L on the $\Delta M_s$ value was obtained by the D0 collaboration (Abazov et al. 2006a). Soon after that the CDF collaboration reported the actual measurement of this quantity ((Abulencia et al. 2006))

$$\Delta M_s^{\text{CDF}} = 17.77 \pm 0.10(\text{stat}) \pm 0.07(\text{syst}) \text{ ps}^{-1}. \quad (95)$$

Later, the LHCb collaboration performed the most precise measurement of $\Delta M_s$ ((Aaij et al. 2013b))

$$\Delta M_s^{\text{LHCb}} = 17.768 \pm 0.023(\text{stat}) \pm 0.006(\text{syst}) \text{ ps}^{-1}. \quad (96)$$

The combination of all $\Delta M_s$ measurements by the HFAG ((Amhis et al. 2014)) gives

$$\Delta M_s^{\text{HFAG 2015}} = 17.757 \pm 0.021 \text{ ps}^{-1}. \quad (97)$$

The currently most precise measurement of $\Delta \Gamma_s$ consists in the simultaneous study of the proper decay length and angular distributions of the decay $B_s^0 \rightarrow J/\psi K^+ K^-$ which mainly includes the $B_s^0 \rightarrow J/\psi \phi$ final state. For simplicity, this study is denoted as $B_s^0 \rightarrow J/\psi \phi$ channel in the following discussion, although it should be remembered that the addition of the non-resonance contribution is required for an appropriate analysis of data. Both the CP-even and CP-odd $B^0_s$ states contribute in this decay mode and that is why its properties are sensitive to both the $B^0_s$ width difference and the phase $\phi_s$ (defined in Section IV.A) describing CP violation in the interference of decay and mixing.

All collider experiments at the Tevatron and LHC perform the measurement of $\Delta \Gamma_s$ in the $B_s^0 \rightarrow J/\psi \phi$ decay. The first results were obtained by the CDF ((Aaltonen et al. 2012)) and D0 ((Abazov et al. 2012a)) collaborations, who largely developed the measurement technique. The ATLAS ((Aad et al. 2014)), CMS ((Khachatryan 2015)) and LHCb ((Aaij et al. 2015b)) collaborations continue this study at LHC, where a significantly larger
statistics is collected and much more data are expected in the future.

As for $\Delta M_s$, the measurement of $\Delta \Gamma_s$ in $B^0_s \to J/\psi \phi$ decay requires IFT and the proper decay length of the $B^0_s$ meson. In addition, the study of the angular distributions of the $B^0_s$ decay products is needed. This is the reason why this analysis is sensitive to the quality of the data description by the simulation. All experiments succeed in achieving an excellent understanding of their detectors. As an example, Fig. 7 shows the distribution of one of the angles describing the $B^0_s \to J/\psi \phi$ decay together with the result of the fit presented by the D0 collaboration.

The measurements of $\Delta \Gamma_s$ using $J/\psi \phi (K^+ K^-)$ are summarised in Table III. It also includes the world average value obtained by the HFAG ([Amhis et al. 2014]), which is found to be

$$\Delta \Gamma_s = 0.079 \pm 0.006 \text{ ps}^{-1} \quad (B^0_s \to J/\psi \phi). \quad (98)$$

The LHCb measurement dominates this average.

An alternative approach to determine $\Delta \Gamma_s$ relies upon the direct measurement of the effective lifetime of $B^0_s$ decays to pure $CP$ eigenstates. The extraction of $\Delta \Gamma_s$ with this method is discussed in detail in Ref. [Fleischer and Knegjens 2011a].

To first order in $y_s \equiv \Delta \Gamma_s/(2 \Gamma_s)$, we have ([Amhis et al. 2014])

\begin{align*}
\tau_{\text{single}}(B^0_s \to CP - \text{even}) & \approx \frac{1}{\Gamma_L} \left( 1 + \frac{(\phi_s)^2 y_s}{2} \right), \quad (99) \\
\tau_{\text{single}}(B^0_s \to CP - \text{odd}) & \approx \frac{1}{\Gamma_H} \left( 1 + \frac{(\phi_s)^2 y_s}{2} \right), \quad (100)
\end{align*}

where $\tau_{\text{single}}$ is the effective lifetime of the $B^0_s$ decaying to a specific $CP$-eigenstate state $f$. This formula assumes that $A^\phi_{CP-\text{EVEN}} = \cos \phi_s$ and $A^\phi_{CP-\text{ODD}} = - \cos \phi_s$, where the mixing angle $\phi_s$ will be defined in Section IV.A. Thus, the decay width measured in the $CP$-even final state, such as $B^0_s \to K^+ K^-$ and $B^0_s \to D^+_s D^0$, is approximately equal to $1/\Gamma_L(s)$. Similarly, the $CP$-odd decay modes $B^0_s \to J/\psi K^0_s$ and $B^0_s \to J/\psi f_0$ provide measurements of $1/\Gamma_H(s)$, thus $\Delta \Gamma_s$ can be obtained as the difference of these two quantities. There are several subtleties that need to be taken into account when using this method to measure $\Delta \Gamma_s$. For example, the decays $B^0_s \to K^+ K^-$ and $B^0_s \to J/\psi K^0_s$ may suffer from $CP$ violation due to interfering tree and loop amplitudes. Thus Ref. [Amhis et al. 2014] uses only the effective lifetimes obtained for $D^+_s D^0$ ($CP$-even), and $J/\psi f_0$, $J/\psi \pi \pi$ ($CP$-odd) decays to obtain

\begin{align*}
\tau_{\text{single}}(B^0_s \to CP - \text{even}) & = 1.379 \pm 0.031 \text{ ps} \quad (101) \\
\tau_{\text{single}}(B^0_s \to CP - \text{odd}) & = 1.656 \pm 0.033 \text{ ps} \quad (102)
\end{align*}

Table IV summarises the current values as well as the average values of $1/\Gamma_L$ and $1/\Gamma_H$ reported in Ref. [Amhis et al. 2014]. Note that the effective lifetimes measured in $B^0_s \to K^+ K^-$ and $B^0_s \to J/\psi K^0_s$ have not been used in these averages because of the difficulty in quantifying

</table>
the penguin contribution in these modes. These effective lifetimes correspond to

$$\Delta \Gamma_s = 0.121 \pm 0.020.$$  \hspace{1cm} (103)

This value is higher by two standard deviations than the one shown in Eq. (98). However, this difference should be considered with caution. The value in Eq. (103) is obtained with theoretical assumptions and external input on weak phases and hadronic parameters.

Using these data in conjunction with the $J/\psi\phi(K^+K^-)$ determinations of $\Delta \Gamma_s$, the current experimental average is \cite{Amhis:2014hma},

$$\Delta \Gamma_s^{\text{HFAG 2015}} = 0.083 \pm 0.006 \text{ ps}^{-1}. \hspace{1cm} (104)$$

The comparison of different lifetime measurements of CP eigenstates, which can be used to extract $\Delta \Gamma_s$ is presented in Fig. 8.

At the end of this section we would like to compare the experimental and theoretical numbers for the mass difference and the decay rate difference. For the experimental value of the mass difference we take the value from Eq. (97) and for the value of the decay width difference we take Eq. (104). For the theory value, we take the more precise prediction of the ratio $\Delta \Gamma_s/\Delta M_s$. We find a very good agreement for experiment and theory

$$\frac{(\Delta \Gamma_s/\Delta M_s)^{\text{Exp}}}{(\Delta \Gamma_s/\Delta M_s)^{\text{SM}}} = 0.00467(1 \pm 0.072) \hspace{1cm} (105)$$

$$= 0.00481(1 \pm 0.173) \hspace{1cm} (106)$$

$$= 0.97 \pm 0.07 \pm 0.17.$$  \hspace{1cm} \text{(106)}$$

In the last line the first error is the experimental one and the second the theoretical one. This results proves that the heavy quark expansion is working in the $B$-sector with a precision of at least 20%, also for the decay channel $b \to c\bar{c}s$, which seems to be most sensitive to violations of quark hadron duality. Assuming that there are no new physics effects in $\Delta M_s$ and taking into account that the ratio $\Delta \Gamma_s/\Delta M_s$ is theoretically cleaner than $\Delta \Gamma_s$ alone, we get an improved prediction for $\Delta \Gamma_s$:

$$\Delta \Gamma_s^{\text{SM,2015b}} = \left(\frac{\Delta \Gamma_s}{\Delta M_s}\right)^{\text{SM}} \cdot \Delta M_s^{\text{Exp}} = 0.085 \pm 0.015 \text{ ps}^{-1}. \hspace{1cm} (107)$$

This is the most precise theory value for $\Delta \Gamma_s$ that can currently be obtained. In future this theory uncertainty might be improved by a factor of up to three.

### III. CP VIOLATION IN MIXING

#### A. Theory: HQE

CP violation in mixing is described by the weak mixing phase $\phi_{12}$

defined in Eq. (13). It can be measured directly via CP asymmetries of so-called flavour-specific or semi leptonic decays. A flavour specific decay $B^0_s \to f$ is described by

**TABLE III** Measurements of $\Delta \Gamma_s$ in $B^0_s \to J/\psi\phi$ decay. The last line gives the world average value obtained by HFAG.
are also called

Examples for such decays are e.g. \( B_s^0 \rightarrow f \) and \( B_s^0 \rightarrow \bar{f} \) are forbidden. This reads in our notation

\[
\tilde{A}_f = 0 = A_f \tag{108}
\]

and thus

\[
\lambda_f = 0 = \frac{1}{\tilde{\lambda}_f} \tag{109}
\]

Thus the time evolution of these decays is quite simple, compared to the general case.

- No direct CP violation arises in the decay, i.e. \( |\langle f | H_{eff} | B_s^0 \rangle| = |\langle \bar{f} | H_{eff} | B_s^0 \rangle| \), which again reads in our notation

\[
|A_f| = |\tilde{A}_f| \tag{110}
\]

Examples for such decays are e.g. \( B_s^0 \rightarrow D_s^- \pi^+ \) or \( B_s^0 \rightarrow X l \nu \) - therefore the corresponding asymmetries are also called semi-leptonic CP asymmetries. The CP asymmetry for flavour-specific decays is defined as

\[
a_{fs}^s = \frac{\Gamma(B_{s}^+(t) \rightarrow f)}{\Gamma(B_{s}^0(t) \rightarrow f)} - \frac{\Gamma(B_{s}^0(t) \rightarrow \bar{f})}{\Gamma(B_{s}^0(t) \rightarrow \bar{f})} = a_{fs}^s \tag{111}
\]

Inserting the time evolution of the \( B_s^0 \) mesons - given in Eq.\((19)\) and Eq.\((26)\) - the flavour specific CP asymmetry \( a_{fs}^s \) can be further simplified\(^8\) as

\[
a_{fs}^s = -2 \left( \left| \frac{q}{p} \right| - 1 \right) = 3 \left( \frac{\Gamma_{12}^s}{M_{12}^s} \right)^2 = \frac{\Gamma_{12}^s}{M_{12}^s} \sin \phi_{12}^s. \tag{112}
\]

For the SM prediction of the flavour-specific asymmetries we can now simply use our determination of the ratio of the matrix elements \( M_{12}^s \) and \( \Gamma_{12}^s \) from the previous section, in particular we need only the coefficient \( a \) (b gives only a small correction) defined in Eq.(77) to get:

\[
a_{fs}^s \approx 3 \left( \frac{\lambda_u}{\lambda_d} \right) \cdot a \cdot 10^{-4}. \tag{113}
\]

The coefficient \( a \) was given by the difference of the internal charm-charm loop and the internal up-charm loop. Using the exact expression for \( 3(\Gamma_{12}^s/M_{12}^s) \) the Standard Model prediction of \( a_{fs}^s \) was given by \( [\text{Lenz and Nierste} \ 2011] \)

\[
a_{fs}^{s,\text{SM,2011}} = (1.9 \pm 0.3) \cdot 10^{-5}. \tag{114}
\]

With the most recent numerical inputs \((G_F, M_W, M_{B_s} \) and \( m_b \) from the PDG ((Olive et al., 2014)), the top quark mass from \( \text{ATLAS and Collaborations, 2014} \)\), the non-perturbative parameters from FLAG (web-update of (Aoki et al., 2014)) and \( B_S/B, B_{B_S}, B_{B_D} \) and \( B_{B}\) from (Bevan et al., 2002), (Bouchard et al., 2011), (Carrazza et al., 2014) and (Dowdall et al., 2014) and CKM elements from CKMfitter (web-update of (Charles et al., 2005)) (similar values can be taken from UTfit (Bona et al., 2006b)) we predict the flavour-specific CP asymmetries of the neutral \( B_s^0 \) mesons to be

\[
a_{fs}^{s,\text{SM,2015}} = (2.22 \pm 0.27) \cdot 10^{-5}. \tag{115}
\]

The dominant uncertainty stems now from the renormalisation scale dependence, with about 9\%, followed by the CKM dependence with about 5\% and the charm quark mass dependence with about 4\%. A detailed discussion of the uncertainties is given in the appendix. Because of this small value and the proven validity of the HQE, the flavour-specific asymmetries represent a nice null test, as any sizable experimental deviation from the prediction in Eq.\((115)\) is a clear indication for new physics.

In addition we obtain the SM prediction for the mixing phase \( \phi_{12}^s \):

\[
\phi_{12}^{s,\text{SM,2015}} = (4.6 \pm 1.2) \cdot 10^{-3} \text{ rad} \tag{116}
\]

\[
= 0.26^\circ \pm 0.07^\circ. \tag{117}
\]

In the discussion of the di-muon asymmetry below we also need the semi-leptonic CP asymmetry from the \( B^0 \) sector. Its calculation within the SM is analogous to the

one of $a_{sl}^d$. We update the predictions given in [Lenz and Nierste 2011], by using the same input parameters as for the $B_S^0$-system, except using $M_{bp}$, $m_d$ and $B_S/B$. We get as new predictions

$$a_{sl}^{d,SM,2015} = (-4.7 \pm 0.6) \cdot 10^{-4}, \quad (118)$$
$$\phi_{12}^{d,SM,2015} = (-0.096 \pm 0.025) \text{ rad}$$
$$=-5.5^0 \pm 1.4^0. \quad (119)$$

A more detailed analysis of the uncertainties can be found in the appendix.

Measurements of the di-muon asymmetry triggered a lot of interest in $B^0$ and $B^0_S$ mixing, because early measurements seemed to indicate large new physics effects. Originally, the di-muon asymmetry $A_{CP}$ was considered to be given by a linear combination of the semi-leptonic CP asymmetries in the $B^0$ and the $B^0_S$ system (see e.g. [Abazov et al. 2010a, 2011])

$$A_{CP} = C_d a_{sl}^d + C_s a_{sl}^s, \quad (120)$$

with $C_d$ and $C_s$ being roughly equal. The large deviation of the measured value of $A_{CP}$ from the calculated values of the linear combination of $a_{sl}^d$ and $a_{sl}^s$ seemed to be a hint for large new physics effects in the semi-leptonic CP asymmetries. In 2013 Borissov and Hoeneisen ([Borissov and Hoeneisen 2013]) found that there is actually also an additional contribution from indirect CP violation. This led to the following new interpretation (also used in [Abazov et al. 2014])

$$A_{CP} = C_d a_{sl}^d + C_s a_{sl}^s + C_{\Delta \Gamma_d} \frac{\Delta \Gamma_d}{\Gamma_d}. \quad (121)$$

Because of the small value of $\Delta \Gamma_d$ in the SM, see Eq. (91) and Eq. (92), the additional term did not solve the discrepancy. Uli Nierste pointed out in a talk at CKM 2014, that the relation should be further modified to

$$A_{CP} = C_d a_{sl}^d + C_s a_{sl}^s + \frac{1}{2} C_{\Delta \Gamma_d} \frac{\Delta \Gamma_d}{\Gamma_d}. \quad (122)$$

An interesting feature of this new interpretation is that a large enhancement of $\Delta \Gamma_d$ by new physics effects is currently not excluded by other constraints. The investigation of [Bobeth et al. 2014] has shown that currently enhancements of $\Delta \Gamma_d$ by several hundred per cent are not excluded by any other experimental constraint - such an enhancement could bring the di-muon asymmetry in agreement with experiment. One possible enhancement mechanism would be e.g. new $bd\tau \tau$ transitions. Since two tau leptons are lighter than a $B^0$ meson such a new operator could contribute to $\Gamma_{T_{12}}^d$. This possibility can be tested by investigating $bd\tau \tau$ transitions directly. In Fig. 9 we show the possible enhancement of $\Delta \Gamma_d$ due to new scalar (l.h.s.) and due to new vector (r.h.s.) $bd\tau \tau$-operators. Currently enhancements within the yellow regions are allowed. In the case of vector operators $\Delta \Gamma_d$ can be enhanced to about 3.5 the SM value of $\Delta \Gamma_d$. The connection between a direct measurement of or a bound on $B^0 \rightarrow \tau^+ \tau^-$ is given by the red line. From Fig. 9 one can read off that a bound on $B^0 \rightarrow \tau^+ \tau^-$ of the order of $10^{-3}$ would limit the enhancement of $\Delta \Gamma_d$ to about 15% of the SM value in the case of scalar new physics operators and to about 50% of the SM value in the case of scalar new physics operators. Similar relations between a possible enhancement of $\Delta \Gamma_d$ and a direct search for $B^0 \rightarrow X_d\tau^+ \tau^-$ and $B^+ \rightarrow \pi^+ \tau^+ \tau^-$ are indicated by the blue line and the green line.

Another enhancement mechanism would be new physics effects in tree-level decays, which are typically neglected. Such studies were performed systematically in [Bobeth et al. 2015, 2014, Brod et al. 2013] and could also lead to sizable enhancements of $\Delta \Gamma_d$. Here a more precise measurement of $\Delta \Gamma_d$ would of course be very helpful.

### B. Experiment: Semi-leptonic asymmetries $a_{sl}^d$ and $a_{sl}^s$, the di-muon asymmetry

The measurement of the flavour-specific charge asymmetry is conceptually simple. Essentially, it involves the measurement of the asymmetry between flavour-specific decays $B^0 \rightarrow f$ and $B^0_S \rightarrow f$. As the expected value of the asymmetry is tiny, great care needs to be taken to assess any potential source of asymmetry, for example, production dynamics, background sources, or detection asymmetry. The final state typically used for this measurement is the semi-leptonic decay $B^0 \rightarrow D_s^{(*)} \mu^+ \nu$ where the notation $(\ast)$ denotes the production of either $D_s^{-}$, $D_s^+$, or $D_{sJ}$ states. The published results consider only the decay $D_s \rightarrow \phi \pi$ with $\phi \rightarrow K^+ K^-$. The initial flavor of the $B^0_S$ meson is not determined and the measured quantity is

$$A_{meas} = \frac{N(D_s^- \mu^+) - N(D_s^+ \mu^-)}{N(D_s^- \mu^+) + N(D_s^+ \mu^-)}. \quad (123)$$

where $N(f)$ ($f = D_s^- \mu^+$ or $D_s^+ \mu^-$) is the number of reconstructed events in the final state $f$. It can be expressed as

$$N(f) \propto \int_0^{\infty} |\sigma(B^0_\text{top}) \Gamma(B^0_\text{top} \rightarrow f) + \sigma(B^0_\text{top}) \Gamma(B^0_\text{top} \rightarrow f)| \epsilon(f,t) dt. \quad (124)$$

This expression takes into account the absence of the initial flavour tagging, the possible difference in the production cross-sections $\sigma(B^0_\text{top})$ and $\sigma(B^0_\text{top})$, and time dependent reconstruction efficiency $\epsilon(f,t)$ of the final state $f$. Note that the measured raw asymmetry is potentially affected by detection asymmetries, in particular differences between $\mu^+ - \mu^-$, and $\pi^+ \pi^-$ detection efficiencies. However, the two kaons from $\phi$ decay have almost the
same momentum spectrum. Thus, their selection does not induce any detection asymmetry.

Using the expressions of the time evolution of $B^0_s$ mesons, assuming that the ratio of the reconstruction efficiencies $r_e = \epsilon(D^0_s, \mu^+, t)/\epsilon(D^0_s, \mu^-, t)$ does not depend on time, and neglecting the second order terms, the semi-leptonic charge asymmetry $a_{s\ell}$ is related to $A_{\text{meas}}$ as

$$A_{\text{meas}} = \frac{a^s_{\ell}}{2} - \frac{1 - r_e}{2} + \left( a_P - \frac{a^s_{\ell}}{2} \right) I \quad (125)$$

$$I = \int_{0}^{+\infty} e^{-\Gamma_{t}t} \cos(\Delta M_{s}t) \epsilon(t) dt \quad \int_{0}^{+\infty} e^{-\Gamma_{t}t} \cosh(\Delta \Gamma_{s}t/2) \epsilon(t) dt.$$ 

Here $a_P$ is the production asymmetry of the $B^0_s$ meson defined as

$$a_P = \frac{\sigma(B^0_s) - \sigma(\bar{B}^0_s)}{\sigma(B^0_s) + \sigma(\bar{B}^0_s)} \quad (126)$$

The asymmetry $a_P$ is zero at a $pp$ collider, while it does not exceed a few percent for the $B^0_s$ production at LHC (see (Aaij et al. 2012g, 2013d, Norrin and Vogt 2000)). Because of the large value of $\Delta M_s$, the value of $I$ is about 0.2%. As a result, the value of the third term in Eq. (125) is of the order of $10^{-4}$ and can be safely neglected. Thus, the main experimental task in the measurement of the $a^s_{\ell}$ is the determination of $r_e$.

Measurements of the asymmetry $a^s_{\ell}$ have been reported by the D0 (Abazov et al. 2013) and LHCb (Aaij et al. 2014c) collaborations. Both D0 and LHCb collected large statistics using semi-leptonic $B^0_s$ decays. The number of reconstructed signal events in the D0 measurement is 215763 ± 1467. The corresponding $\mu^+ \phi \pi^\mp$ mass distribution is shown in Fig. 10. The number of reconstructed signal events in the LHCb measurement is 184817 ± 484. The corresponding mass distribution is shown in Fig. 11.

![FIG. 9 The possible enhancement factor of $\Delta\Gamma_d$ by new scalar (l.h.s.) or vector (r.h.s.) $b\bar{d}r\tau$ operators are indicated by the yellow region. In the case of a scalar operator $\Delta\Gamma_d$ can still be enhanced to about 1.6 times of the SM values. In the case of a vector operator $\Delta\Gamma_d$ can even be enhanced to about 3.5 times of the SM values. More precise bounds on $B^0 \rightarrow \tau^+\tau^-$, $B^0 \rightarrow X_d \tau^+\tau^-$ and $B^0 \rightarrow \pi^+\pi^+\pi^-$ could further shrink the allowed enhancement factor. The relation between the bounds $B^0 \rightarrow \tau^+\tau^-$, $B^0 \rightarrow X_d \tau^+\tau^-$ and $B^0 \rightarrow \pi^+\pi^+\pi^-$ and the possible enhancement factor of $\Delta\Gamma_d$ is given by the red, blue and green line.](image)

![FIG. 10 The weighted $K^+ K^- \pi^\mp$ invariant mass distribution for the $\mu \phi \pi^\mp$ sample. The solid line represents the result of the fit and the dashed line shows the background parametrisation. The lower mass peak is due to the decay $D^\mp \rightarrow \phi \pi^\mp$ and the second peak is due to the $D_s^\mp$ meson decay. Note the suppressed zero on the vertical axis. The plot is taken from (Abazov et al. 2013).](image)

The important feature of both experiments is a regular reversal of the magnet polarities. In the D0 experiment, the polarities of the toroidal and solenoidal magnetic fields were reversed on average every two weeks so that the four solenoid-toroid pair combinations are exposed to approximately the same integrated luminosity. D0 reported only results averaged over all the magnet polarities. The 1 fb$^{-1}$ LHCb sample comprises approximately 40% of data taken with the magnetic field up, oriented along the positive $y$-axis in the LHCb coordinate system, and the rest with the opposite down polarity. LHCb analyses data with magnetic field up and down separately, to allow a quantitative assessment of charge-dependent asymmetries. Figure 12 shows their measurement of the ratio $r_e$ for two magnet polarities.
It can be seen that the majority of the detection asymmetry changes sign with the reversal of the magnet polarity, and thus the final average of the two samples is much less sensitive to detection asymmetry.

The resulting values of $a_{sl}^d$ obtained by the two experiments as well as their combination by the HFAG (Amhis et al. 2014) are

$$a_{sl}^{D_0} = -1.12 \pm 0.74 \pm 0.17\%,$$ (127)

$$a_{sl}^{LHCb} = -0.06 \pm 0.50 \pm 0.36\%,$$ (128)

$$a_{sl}^{HFAG} = -0.48 \pm 0.48\%.$$ (129)

Both results are consistent with the Standard Model expectation (115), albeit the uncertainty is still a factor of about 250 larger than the central value in the Standard Model. The LHCb experiment uses only 1 fb$^{-1}$ of statistics out of 3 fb$^{-1}$ collected in Run I. An updated result based on the full 3 fb$^{-1}$ sample, including use of the final state $D_s^+ \rightarrow K^+ K^- \pi^+$ is imminent.

The Babar, Belle, D0, and LHCb collaborations perform the independent measurement of the asymmetry $a_{sl}^d$. Their results are summarised in Table V. The world average value of $a_{sl}^d$ is

$$a_{sl}^d{(HFAG)} = 0.0001 \pm 0.0020.$$ (130)

The D0 experiment also reports a complementary measurement related to the semi-leptonic asymmetries of $B_s^0$ and $B^0$ mesons (Abazov et al. 2014). It performs the simultaneous study of the inclusive semi-leptonic charge asymmetry and of the like-sign di-muon charge asymme-
In the D0 analysis. Their result is 

\[
d_{a} = (0.62 \pm 0.43) \times 10^{-2},
\]

\[
s_{a} = (0.82 \pm 0.99) \times 10^{-2},
\]

\[
\Delta \Gamma \Gamma d = (+0.50 \pm 1.38) \times 10^{-2}.
\]

The correlation between the fitted parameters are

\[
\rho_{d,s} = -0.61, \quad \rho_{d,\Delta \Gamma} = -0.03, \quad \rho_{s,\Delta \Gamma} = +0.66.
\]

Although the central values of all three quantities are consistent with the SM prediction within the uncertainties, a deviation from the SM prediction by 3 standard deviations is reported because of the correlation between these observables. Fig. 14 shows the 68% and 95% confidence level contours in the \(d_{a} - s_{a}\) obtained in the D0 analysis.

The summary of the world knowledge of CP violating parameters in \(B_{d}^{0}\) and \(B^{0}\) mixing is summarised in Fig. 15 that shows that the individual measurements of \(d_{a}^{0}\) and \(s_{a}^{0}\) are consistent with the Standard Model. Only the D0 di-muon result suggests a deviation from Standard Model expectations in CP violation in neutral \(B^{0}\) oscillations. Since this measurement is inclusive, other unknown effects not directly related to the CP violation in \(B\) mesons could contribute to it.

In addition to the current refinement of \(s_{a}^{0}\) with the full 3 fb\(^{-1}\) run I sample, the LHCb experiment is expected to collect an additional sample of \(~6\) fb\(^{-1}\) in the current LHC run, and at least 50 fb\(^{-1}\) with an upgraded detector to be installed in 2020. Therefore CP violating asymmetries in neutral \(B\) meson decays will be measured with much better precision in future studies.

**TABLE V Most recent measurements of the CP violation parameter \(a_{d}^{0}\).**
Collinear Effective Theory (SCET; e.g. (Bauer et al. 1999b, 2000, 2001; Beneke and Neubert, 2003)), Soft jamirian, 2001)) and perturbative QCD (pQCD; e.g. (Li problem: QCD factorisation (QCDF; e.g. (Beneke are available in order to investigate this non-perturbative calculation of the strong amplitudes and phases from first principles is a non-trivial problem, which has not been

A. Theory

In this section we discuss CP violating effects that arise from interference between mixing and decay, which is also called mixing-induced CP violation. We consider therefore in the following a final state \( f \) in which in principle both the \( B_s^0 \)-meson and the \( \bar{B}_s^0 \)-meson can decay. The corresponding decay amplitudes will be denoted by \( A_f \) and \( \bar{A}_f \), defined in Eq. [22]. These amplitudes can have contributions from different CKM structures, their general structure looks like

\[
A_f = \sum_j A_f e^{i(\phi_j^{\text{strong}} + \phi_j^{\text{CKM}})},
\]

where \( j \) sums over the different CKM contributions, \( \phi_j^{\text{CKM}} \) denotes the corresponding CKM phase and \( A_f e^{i\phi_j^{\text{strong}}} \) encodes the whole non-perturbative physics as well as the moduli of the CKM-elements. The calculation of the strong amplitudes and phases from first principles is a non-trivial problem, which has not been solved generally till now. Currently several working tools are available in order to investigate this non-perturbative problem: QCD factorisation (QCDF; e.g. (Beneke et al. 1999b, 2000, 2001; Beneke and Neubert, 2003)), Soft Collinear Effective Theory (SCET; e.g. (Bauer et al. 2001, 2004, 2002)), light cone sum rules (LCSR; e.g. (Balitsky et al. 1989) Khodjamirian et al. 2003) Khodjamirian and Yu 2001 and perturbative QCD (pQCD; e.g. (Li and Yu 1996) Yeh and Li, 1997).

Considering now the CP conjugate decay \( \bar{B}_s^0 \to \bar{f} \) one finds

\[
\bar{A}_f = - \sum_j A_f e^{i(\phi_j^{\text{strong}} - \phi_j^{\text{CKM}})},
\]

so only the CKM phase has changed its sign, while the strong amplitude and the strong phase remain unmodified. The overall sign is due to the CP-properties of the \( B_s^0 \)-mesons, defined in Eq. (5) and \( \bar{f} \) defined in Eq. (34).

In some CP asymmetries the hadronic amplitudes cancel to a good approximation in the ratios of decay rates. The corresponding decay modes are the so-called golden modes, which were introduced e.g. by (Carter and Sanda, 1981) and (Bigi and Sanda, 1981). Later on we will see that golden modes will appear, when the decay amplitude is governed by a single CKM structure. This could be the case in a decay like \( B_s^0 \to J/\psi \phi \), which is governed on quark-level by a \( b \to c\bar{c}s \)-transition. Such a transition has a large tree-level contribution and a suppressed penguin contribution, see Fig. 16. To a good first approximation the penguins can be neglected and we have a golden mode, with a precise relation of the corresponding CP-asymmetry to fundamental Standard Model parameters, including the CKM-couplings. In view of the dramatically increased experimental precision in recent years it turns out, however, that it is necessary to investigate the possible size of penguin effects, the so-called penguin pollution. This will be discussed below.

Let us come back to the general case and consider the following time-dependent CP asymmetry for a \( B_s^0 \to f \) transition without any approximations concerning the structure of the decay amplitude.

\[
A_{CP,f}(t) = \frac{\Gamma(\bar{B}_s^0(t) \to f) - \Gamma(B_s^0(t) \to f)}{\Gamma(\bar{B}_s^0(t) \to f) + \Gamma(B_s^0(t) \to f)} + \mathcal{O}(a),
\]

Inserting the time evolution given in Eq. (21) and Eq. (33) one finds

\[
A_{CP,f}(t) = -A_{CP}^{\text{dir}} \cos(\Delta M_s t) + A_{CP}^{\text{mix}} \sin(\Delta M_s t) + \mathcal{O}(a),
\]

with \( A_{CP}^{\text{dir}} \), \( A_{CP}^{\text{mix}} \) and \( A_{CP}^{\text{dir}} \) being defined in Eq. (24), Eq. (25) and Eq. (26). We can rewrite two of those definitions as

\[
A_{CP}^{\text{mix}} = -\frac{2|\lambda_f|}{1 + |\lambda_f|^2} \sin[\arg(\lambda_f) - \frac{2|\lambda_f|}{1 + |\lambda_f|^2} \sin[\phi_s] + \frac{2|\lambda_f|}{1 + |\lambda_f|^2} \sin[\phi_s],
\]

(143)

\[
A_{CP}^{\text{dir}} = -\frac{2|\lambda_f|}{1 + |\lambda_f|^2} \cos[\arg(\lambda_f) - \frac{2|\lambda_f|}{1 + |\lambda_f|^2} \cos[\phi_s],
\]

(144)

A more detailed derivation can be found in (Anikeev et al. 2001).
with the phase \( \phi_s \) to be defined as
\[
\phi_s = -\arg(\lambda_f) = -\arg\left(\frac{q}{p} \frac{\bar{A}_f}{A_f}\right) \quad (145)
\]
\[
= -\pi + \phi_M - \arg\left(\frac{\bar{A}_f}{A_f}\right). \quad (146)
\]
This is the most general definition of the phase that appears in interference. In this form a measurement of \( \phi_s \) does, however, not enable us to connect the phase with fundamental parameters of the underlying theory. To do so, we either find some simplifications for the decay amplitudes or we have to solve the ratio of amplitudes non-perturbatively. Before discussing a particular simplification, we note that sometimes a different notation (\( S_f \) for the coefficient that is arising in Eq. (142) with the term \( \sin(\Delta M t) \) and \( C_f \) or \( A_f \) for the coefficient that is arising with the term \( \cos(\Delta M t) \)) is used
\[
A_f = C_f \equiv A_{CP}^{\text{dir}}, \quad (147)
\]
\[
= -S_f \equiv A_{CP}^{\text{mix}}. \quad (148)
\]
BaBar uses \( C_f \) and Belle \( A_f \). Expanding the hyperbolic functions in Eq. (142) for small arguments, i.e. small decay rate differences and/or short times, we can express the time-dependent CP asymmetry \( A_{CP,f}(t) \) as
\[
A_{CP,f}(t) \approx \frac{S_f \sin(\Delta M t) - C_f \cos(\Delta M t)}{1 + \Delta_\tau \frac{\Delta\Gamma}{\Delta\tau} + \frac{1}{2} \left(\frac{\Delta\Gamma}{\Delta\tau}\right)^2}. \quad (149)
\]
This formula holds for general decays and no approximation concerning the corresponding decay amplitudes has been made yet. In this general case the quantities \( A_{CP}^{\text{dir}} \), \( A_{CP}^{\text{mix}} \) and \( \Delta_\tau \) are unknown hadronic objects that are very difficult to be determined in theory.

In the following we discuss the simplified case of the golden modes. Here we consider the final state \( f \) to be a CP eigenstate, i.e. \( f = f_{CP} = \eta_{CP} f \) and we assume that only one CKM structure is contributing to the decay amplitude - e.g. neglecting penguins. In this special case we get
\[
A_{f_{CP}} = A_f e^{i(\phi_{\text{tree}} + \phi_{\text{CKM}})}, \quad (150)
\]
\[
= \eta_{CP} A_{f_{CP}} = \eta_{CP} A_f e^{i(\phi_{\text{tree}} - \phi_{\text{CKM}})}, \quad (151)
\]
\[
\Rightarrow A_{f_{CP}} = -\eta_{CP} e^{-2i\phi_{\text{CKM}}}. \quad (152)
\]
So in the case of golden modes all hadronic uncertainties cancel exactly in the ratio of the two decay amplitudes in Eq. (152) and one is left with a pure weak CKM phase. Thus the parameter \( \lambda_f \), which triggers the CP-asymmetries is given by
\[
\lambda_{f_{CP}} = \frac{q}{p} \frac{\bar{A}_{f_{CP}}}{A_{f_{CP}}} = \eta_{CP} \frac{V_{ts}V^*_{tb}}{V^*_{ce}V_{cb}} e^{-2i\phi_{\text{CKM}}}. \quad (153)
\]
Therefore we have in the case of only one contributing CKM structure \( |\lambda_{f_{CP}}| = 1 \) and thus
\[
A_{CP}^{\text{dir}} = 0, \quad (154)
\]
\[
A_{CP}^{\text{mix}} = +\sin(\phi_s), \quad (155)
\]
\[
\Delta_\tau = -\cos(\phi_s). \quad (156)
\]
leading to the simplified formula for the asymmetry
\[
A_{CP,f}(t) \approx \frac{\sin\phi_s \sin(\Delta M t)}{\cos\phi_s \sinh(\Delta M t/2) - \cosh(\Delta M t/2)}. \quad (157)
\]
This formula holds in the case of only one contributing CKM-structure to the whole decay amplitude and the final state being a CP-eigenstate.

If the corresponding decay is triggered e.g. by a \( b \to c\bar{c}s \) transition on quark-level, as in the case of \( B^0_s \to J/\psi\phi \), we get
\[
\phi_s = -\arg\left(\eta_{CP} \frac{V_{ts}V^*_{tb} V^*_{ce}V_{cb}}{V^*_{ce}V_{cb}}\right). \quad (158)
\]
Thus a measurement of the mixing phase \( \phi_s \) gives us direct information about the phases, i.e. the amount of CP-violation, of the CKM elements. If in addition the final state has a CP eigenvalue \( \eta_{CP} = 1 \), then we get
\[
\phi_s = -2\beta_s, \quad (159)
\]
with the commonly used notation
\[
\beta_s = -\arg\left[-\frac{V_{ts}V^*_{tb}}{V^*_{ce}V_{cb}}\right] \quad (160)
\]
\[
= 0.0183 \pm 0.0010 = (1.05 \pm 0.05)^\circ. \quad (161)
\]
Here we used a definition for \( \beta_s \) that ensures that its numerical value is positive; sometimes a different sign is used.

If only a modest experimental precision available, then penguins can be neglected to a first approximation for the tree-level dominated \( b \to c\bar{c}s \) decays like \( B_s \to J/\psi\phi \) penguins and we can use simplified formule like Eq. (159). However, we will see below that the current experimental precision in the determination of \( \phi_s \) is of the order of \( \pm 2^\circ \), which equals the SM expectation of \( \phi_s^{SM} = (2.1\pm0.1)^\circ \). In view of this high experimental precision, it seems mandatory to determine the possible size of penguin contributions (penguin pollution), in order to make profound statements about new physics effects in these CP-asymmetries.

Let us thus have a look at the general expression for the decay amplitude without neglecting penguins. Examples for decays with both tree-level and penguin contributions are e.g. \( B_s \to J/\psi\phi \) or \( B_s \to K^-\pi^+ \). The first decay is governed on quark-level by a \( b \to c\bar{c}s \)-transition and the latter one by a \( b \to u\bar{d}d\)-transition. The tree-level components and penguin contributions to this decay are shown in Fig. 16.
A naive dimensional estimate (size of CKM couplings, number of strong couplings and colour counting) gives a small penguin contribution in the case of \( B_s \rightarrow J/\psi \phi \) and a large penguin contribution in the case \( B_s \rightarrow K^- \pi^+ \). Thus \( B_s \rightarrow J/\psi \phi \) is a prime candidate for a golden mode, while in the case of \( B_s \rightarrow K^- \pi^+ \) direct CP violation, i.e. CP violation directly in the decay might be visible; this will be further discussed in Section V.

To become more quantitative we will have a closer look at the general structure of the decay amplitude of a \( b \rightarrow c\bar{c}s\) transition. Using the effective Hamiltonian for \( \Delta B = 1 \) transitions (see e.g. [Buras, 1998] for a nice introduction) we get for the amplitude:

\[
A_f (B_s^0 \rightarrow f) = \langle f | H_{\text{eff}} | B_s^0 \rangle ,
\]

with the effective SM Hamiltonian for \( b \rightarrow c\bar{c}s \) transitions:

\[
H_{\text{eff.}} = \frac{G_F}{\sqrt{2}} \left[ \lambda_u \sum_{i=1,2} C_i (Q_i^u)^P + \lambda_c \sum_{i=1,2} C_i (Q_i^c)^{T+P} + \lambda_t \sum_{i=3}^6 C_i Q_i^t \right] + h.c. .
\]

(163)

The CKM structure is given as before by \( \lambda_q := V_{qb} V_{qs}^* \); the decay \( b \rightarrow c\bar{c}s \) proceeds via the current-current operators \( Q_i^u, Q_i^c \) and the QCD penguin operators \( Q_3, ..., Q_6 \). \( C_1, ..., C_6 \) are the corresponding Wilson coefficients. When the current-current operators \( Q_i^u, Q_i^c \) are inserted in a penguin diagram in the effective theory, they also contribute to \( b \rightarrow c\bar{c}s \). Electro-weak penguins are neglected.

Therefore we have the following structure of the amplitude \( A_f (B_s^0 \rightarrow f) \)

\[
A_f = \frac{G_F}{\sqrt{2}} \left[ \lambda_u \sum_{i=1,2} C_i (Q_i^u)^P + \lambda_c \sum_{i=1,2} C_i (Q_i^c)^{T+P} + \lambda_t \sum_{i=3}^6 C_i Q_i^t \right] + h.c. .
\]

(164)

\( (Q)^T \) denotes the tree-level insertion of the local operator \( Q_i \), \( (Q)^P \) denotes the insertion of the operator \( Q \) in a penguin diagram. Using further the unitarity of the CKM matrix, \( \lambda_t = -\lambda_u - \lambda_c \), we can rewrite the amplitude in a form where only two different CKM structures are appearing.

\[
A_f = \frac{G_F}{\sqrt{2}} \sum_{i=1,2} C_i (Q_i^u)^{T+P} - \sum_{i=3}^6 C_i (Q_i^t)^T + \frac{\lambda_u}{\lambda_c} \left( \sum_{i=1,2} C_i (Q_i^u)^P - \sum_{i=3}^6 C_i (Q_i^t)^T \right)
\]

(165)

\[
= A_f^\text{Tree} + A_f^\text{Peng} .
\]

(166)

In the last line we have defined separately a tree-level...
amplitude and a penguin amplitude. They are given by
\[ A_f^{\text{Tree}} = \frac{G_F}{\sqrt{2}} \lambda_c \left[ \sum_{i=1,2} C_i \langle Q_i^u \rangle_T^P - \sum_{i=3} C_i \langle Q_i^u \rangle_T \right] \]
\[ = |A_f^{\text{Tree}}| e^{i[\phi_{QCD}^{\text{SM}} + \arg(\lambda_c)]}, \quad (167) \]
\[ A_f^{\text{Peng}} = \frac{G_F}{\sqrt{2}} \lambda_u \left[ \sum_{i=1,2} C_i \langle Q_i^u \rangle_P^P - \sum_{i=3} C_i \langle Q_i^u \rangle_T \right] \]
\[ = |A_f^{\text{Peng}}| e^{i[\phi_{QCD}^{\text{SM}} + \arg(\lambda_u)]}. \quad (168) \]

Here we have split up the amplitudes into their modulus and their phase. Sometimes it advantageous to split also off the explicit dependence on the modulus of the CKM structure:
\[ |A_f^{\text{Tree}}| = \frac{G_F}{\sqrt{2}} |\lambda_c| |A_f^{\text{Tree}}|, \quad (169) \]
\[ |A_f^{\text{Peng}}| = \frac{G_F}{\sqrt{2}} |\lambda_u| |A_f^{\text{Peng}}|. \quad (170) \]

The strong amplitudes and the strong phases are in principle unknown, a first naive estimate of the size of the modulus can be done by investigating, what \( \Delta B = 1 \) Wilson coefficients are contributing. In the case of \( B^0 \to J/\psi \) the tree-level amplitude is enhanced by the CKM-elements in \( \lambda_c \) and the tree-level contribution of the large Wilson coefficients \( C_1 \) and \( C_2 \); the penguin amplitude is suppressed by \( \lambda_u \) and further either by small penguin Wilson-coefficients \( C_3, \ldots, 6 \) or by a loop.

In general, i.e. without any approximations concerning the size of the hadronic effects, we get for the ratio of decay amplitudes
\[ \frac{\hat{A}_f}{A_f} = -e^{-2i \arg(\lambda_c)} \left[ \frac{1 + re^{-i \arg(\lambda_u)}}{1 + re^{i \arg(\lambda_u)}} \right] \quad (171) \]
with \( r \) being defined as
\[ r = \frac{|\lambda_u|}{|\lambda_c|} \frac{|A_f^{\text{Peng}}|}{|A_f^{\text{Tree}}|} e^{i[\phi_{QCD}^{\text{SM}} - \phi_{QCD}^{\text{Tree}}]}. \quad (172) \]

In the case of \( B^0 \to J/\psi \) the CKM part of \( r \) is very small, it is given by \( |\lambda_u/\lambda_c| \approx 0.02 \). The hadronic part of \( r \) is a non-perturbative quantity that can currently not be calculated from first principles. Before we turn to some quantitative investigations in the literature, we have a look at a naive estimate: \( \hat{A}_f^{\text{Peng}} \) and \( A_f^{\text{Tree}} \) contain Wilson coefficients from the effective Hamiltonian. The penguin Wilson coefficients \( [C_3, \ldots, 6] \) are typically smaller than 0.04, therefore one can neglect them in comparison to the Wilson coefficient \( C_2 \approx 1 \). Thus we are left with the tree-level insertion of the operator \( Q_2 \) in the case of \( A_f^{\text{Tree}} \) and with the penguin insertion of the operator \( Q_2 \) in the case of \( A_f^{\text{Peng}} \). Since we do not know the relative size of these two, we take the analogy of inclusive \( b \)-quark decays as a first indication of its size. For the inclusive decay \( b \to c \bar{c}s \) it turned out (see e.g. (Bagan et al., 1995; Krinner et al., 2013; Lenz et al., 1997)) that \( \langle Q_i^u \rangle \approx 0.05 \langle Q_i^u \rangle \). Taking this value as an indication for the size of \( A_f^{\text{Peng}}/A_f^{\text{Tree}} \) we get an estimate of \( r \) of about \( |r| \approx 0.001 \). One should be aware, however, that this very naive estimate can easily be off by a factor of 10 and we also cannot quantify the size of the strong phase in this approach. Using the same methods for the decay \( B^0 \to K^- \pi^+ \) we would get a value of \( |r| \approx 0.01 \), so roughly 100 times larger than in the case of \( B^0 \to J/\psi \). \( B^0 \to K^- \pi^+ \) is thus a prime candidate for decays where we are looking for large penguin effects, e.g. if we want to measure a direct CP asymmetry in the \( B^0 \) system. Our naive estimate does not take into account that these two channel proceed via different topologies; hence the factor 100 might have to be modified considerably.

Nevertheless it seems that \( r \) is a small number in the case of \( B^0 \to J/\psi \) and we can make a Taylor expansion in Eq. (171) to obtain
\[ \frac{\hat{A}_f}{A_f} \approx -e^{-2i \arg(\lambda_c)} \left[ 1 - 2ir \sin \left( \arg \left( \frac{\lambda_u}{\lambda_c} \right) \right) \right] \quad (173) \]

Investigating further Eq. (173) or Eq. (171), we see that the first term on the r.h.s. gives rise to \(-2\beta_s\), in the CP asymmetry in Eq. (157). The second term (proportional to \( r \)), corresponds to the SM penguin pollution, which we denote by \( \delta_{\text{Peng,SM}} \). Therefore the experimentally measured phase \( \phi_s \) has two contributions in the Standard Model:
\[ \phi_s = -2\beta_s + \delta_{\text{Peng,SM}}, \quad (174) \]
where the Standard Model penguin is given by
\[ e^{i\phi_{\text{Peng,SM}}} \approx 1 - 2ir \sin \left( \arg \left( \frac{\lambda_u}{\lambda_c} \right) \right) e^{i[\phi_{QCD}^{\text{SM}} - \phi_{QCD}^{\text{Tree}}]} \quad (175) \]

Inserting the above approximations for \( B^0 \to J/\psi \) we get as a very rough estimate of the penguin pollution:
\[ e^{i\phi_{\text{Peng,SM}}} \approx 1 - 0.002ir e^{i[\phi_{QCD}^{\text{SM}} - \phi_{QCD}^{\text{Tree}}]} \Rightarrow \delta_{\text{Peng,SM}} \leq \pm 0.002 = \pm 0.1^\circ. \quad (176) \]

Thus very naively we expect a penguin pollution of at most \( \pm 0.1^\circ \) in the case of \( B^0 \to J/\psi \). This very rough estimate could, however, be easily modified by a factor of e.g. 10, due to non-perturbative effects and then we would be close to the current experimental uncertainties. Thus more theoretical work has to be done to quantify the size of penguin contributions. There are now several strategies to achieve this point:

1. Measure \( \phi_s \) in different decay channels: assuming that penguins are negligible, different extractions
should give the same value for the mixing phase. Until now we concentrated our discussion of the extraction of the phase $\phi_s$ on the decay $B^0_s \rightarrow J/\psi\phi$. This final state is an admixture of CP-even and CP-odd components. To extract information on $\Delta t_s$ and $\phi_s$ an angular analysis is required, see the discussion in Section II.B and Section IV.B or the early references: [Dighe et al. 1999] [1996 Dunietz et al. 2001]. Moreover the $J/\psi\phi(\rightarrow K^+K^-)$ final state can be investigated for non-resonant $K^+K^-$ contributions in order to increase the statistics. The phase $\phi_s$ has also been determined in different $b \rightarrow c\bar{c}s$-channels, like $B^0_s \rightarrow J/\psi\pi^+\pi^-$ (including $B^0 \rightarrow J/\psi f_0$, see e.g. Colangelo et al. 2011 Fleischer et al. 2011a [Stone and Zhang 2009 2013 Zhang and Stone 2013], $B^0_s \rightarrow J/\psi\eta^{(')}$ (see e.g. [Di Donato et al. 2012 Dunietz et al. 2001 Fleischer et al. 2011b]) and $B^0_s \rightarrow D_s^{(*)}\pi^+$ (see e.g. Dunietz et al. 2001 Fleischer 2007b) as a cross-check.

Here $B^0_s \rightarrow J/\psi f_0$ is a CP-odd final state, $J/\psi\eta^{(')}$ and $D_s^+D_s^-$ are CP-even final states, and $D_s^+\bar{D}_s^-$ is again an admixture of different CP components. Getting different values for $\phi_s$ from different decay modes would point towards different and large penguin contributions in the individual channels. The different experimental results will be discussed in the next section, they show no significant deviations within the current experimental uncertainties, but there is also plenty of space left for some sizeable differences.

2. Measure the phase $\phi_s$ for different polarisations of the final states in $B^0_s \rightarrow J/\psi\phi$: potential differences might originate from penguins, which in general contribute differently to different polarisations, see [Faller et al. 2009a Fleischer 1999b]. Such an analysis was done in [Aaij et al. 2015b] and within the current experimental uncertainties no hint for a polarisation dependence of $\phi_s$ was found:

$$\phi_{s,||} - \phi_{s,0} = -(1.03 \pm 2.46 \pm 0.52)^\circ,$$ (177)
$$\phi_{s,\perp} - \phi_{s,0} = -(0.80 \pm 2.01 \pm 0.34)^\circ.$$ (178)

On the other hand one sees that effects of the order of $2^\circ$, which would be as large as the whole SM prediction for $\phi_s$, are not ruled out yet. A further discussion of this result was done by [DeBruyn and Fleisher 2015].

3. Compare the decay $B^0 \rightarrow J/\psi\phi$ to a decay with a similar hadronic structure, but an CKM enhanced penguin contribution: differences in the phase $\phi_s$ extracted from $B^0_s \rightarrow J/\psi\phi$ and from the new decay might then give experimental hints for the size of the penguin contribution.

Exchanging the s-quark line in Fig 10 with a d-quark line one arrives at decays like $B^0_s \rightarrow J/\psi K_S$ (see e.g. Fleischer 1999b) or $B^0_s \rightarrow J/\psi K^*(892)$ (see e.g. [DeBruyn and Fleisher 2015 Dunietz et al. 2001 Faller et al. 2009a]). In the first decay there is only one vector particle in the final state, while the latter case we have two ($K^*(892)$ is a vector meson) as in the case of $B^0 \rightarrow J/\psi\phi$. Thus we consider here only the decay $B^0_s \rightarrow J/\psi K^*(892)$. The analogous similarity in the case of $B^0$-mesons is $B^0 \rightarrow J/\psi K_s \leftrightarrow B^0 \rightarrow J/\psi\pi^0$. The extraction of penguin pollution via this relation was discussed in e.g. [Ciuchini et al. 2005 2011 Faller et al. 2009b]. To get an idea of the appearing size of the penguin uncertainties, we note that [Ciuchini et al. 2011] found a possible Standard Model penguin pollution of about $±1^\circ$ in the golden mode $B^0 \rightarrow J/\psi K_s$.

Coming back to the $B^0_s$ system: in the decays $B^0_s \rightarrow J/\psi K_S$ and $B^0_s \rightarrow J/\psi K^*(892)$ the relative size of the penguin contributions compared to the tree-level part is by a factor of about $1/\lambda^2 \approx 25$ larger compared to $B^0 \rightarrow J/\psi\phi$. This enhancement of the penguin contribution might show up in different values for the extracted values of the phase $\phi_s$. A disadvantage of these decays is that they are more difficult to measure, because they proceed on quark-level via $b \rightarrow c\bar{c}d$, whose branching ratio is suppressed by a factor of about $\lambda^2 \approx 1/25$ compared to $B^0_s \rightarrow J/\psi\phi$. This is the reason, why the CP asymmetries in $B^0_s \rightarrow J/\psi K_S$ and the one in $B^0_s \rightarrow J/\psi K^*(892)$ have only been measured recently with large uncertainties by [Aaij et al. 2015c] and by [Aaij et al. 2015d]. The corresponding branching ratios have been measured earlier by the LHCb Collaboration ([Aaij et al. 2012c]). [DeBruyn and Fleisher 2015] discuss some strategies to extract the size of penguin pollution without having the full knowledge about these CP asymmetries. A further drawback of this method is that the size of the hadronic effects due to the exchange of a $\phi$-meson with a $K^*$($892$)-meson cannot be quantified from first principles. Finally there are also penguin annihilation and weak exchange topologies contributing to $B^0 \rightarrow J/\psi\phi$, that are not present in the $B^0 \rightarrow J/\psi K^*(892)$ case, see e.g. [Faller et al. 2009a]. Whether it is justified to neglect such contributions can e.g. be tested by decays like $B^0 \rightarrow J/\psi\phi$ that proceed only via weak-exchange and annihilation topologies. Experimental constraints on $B^0 \rightarrow J/\psi\phi$ from Belle ([et al. 2008]), BaBar ([Lees et al. 2015a]) and LHC ([Aaij et al. 2013c]) indicate, however, no unusual enhancement of annihilation or weak exchange contributions.
4. Compare the decay $B^0 \to J/\psi \phi$ with a decay which is related to it via a symmetry of QCD: having now a symmetry might add confidence in obtaining some control over the effect of exchanging the initial and final states mesons with other mesons. Such a symmetry is the flavour symmetry $SU(3)_F$, i.e. a symmetry of QCD under the exchange of $u$, $d$ and $s$-quarks. The application of these symmetry is quite widespread, see e.g. [Bhattacharya et al., 2013; Chiuchini et al., 2005; 2011; De Bruyn and Fleischer, 1999; Jung, 2012; Ligeti and Robinson, 2015] for some examples related to $B$-meson decays. Again a word of caution: it is currently not clear how well the $SU(3)_F$-symmetry is working and how large the corrections are, see e.g. [Faller et al., 2009a; Fynings et al., 2015] for some critical comments. On the other hand a comparison of experimental data finds that $SU(3)_F$ might work quite well, for some of these decay channels, see e.g. [De Bruyn and Fleischer, 2015]. A sub-group of $SU(3)_F$, which is supposed to work particularly well, is the so-called $U$-spin symmetry, i.e. the invariance of QCD under the exchange of the $s$-quark with a $d$-quark, see e.g. [De Bruyn and Fleischer, 2015; Fleischer, 1999a,b]. Substituting the $s$- and $s$-quark on the l.h.s. of Fig.16 with down-type quarks one gets, e.g. [Fleischer, 1999a].

$$B^0 \to J/\psi \phi \Leftrightarrow B^0 \to J/\psi \rho^0, J/\psi \pi^0.$$  
\[179\]

The decay $B^0 \to J/\psi \rho^0$ has also enhanced penguin contributions and a similar structure as $B^0 \to J/\psi \pi^0$ and $B^0 \to J/\psi \phi$: tree and penguin contributions to $B^0 \to J/\psi \pi^0 \pi^\mp$ which contains $B^0 \to J/\psi \rho^0$ are depicted in Fig.17. $B^0 \to J/\psi \rho^0$ is discussed further e.g. by [De Bruyn and Fleischer, 2015] and there are also first measurements of the mixing induced CP asymmetries by the LHCb Collaboration ([Aaij et al., 2015c]). In this decay we have again two vector mesons in the final state, as in the case $B^0 \to J/\psi \phi$. Thus here we do not consider the decay $B^0 \to J/\psi \pi^0$ any further. However this decay gave important constraints on the penguin pollution in $B^0 \to J/\psi K_S$ - as it was explained above.

Applying U-spin symmetry to the $B^0$ system one gets e.g.

$$B^0 \to J/\psi K_s \Leftrightarrow B^0 \to J/\psi K_s.$$  
\[180\]

The decay $B^0 \to J/\psi K_s$ was already mentioned above for estimating penguin uncertainties in $B^0 \to J/\psi \phi$. It is, however, much better suited for the decay $B^0 \to J/\psi K_s$, see [De Bruyn and Fleischer, 2015; Faller et al., 2009b; Fleischer, 1999b]. Further experimental studies of this decay were performed by [Aaij et al., 2013g]. Currently symmetry considerations put a quite strong bound on the penguin pollution; [De Bruyn and Fleischer, 2015] (see also [Fleischer, 2015]) get for the decay $B^0 \to J/\psi \phi$ the following possible size of penguin pollution:

$$\delta_{Peng,SM}^{J/\psi \phi} = [0.08^{+0.56}_{-0.72} \text{(stat)} + 0.15^{+0.13}_{-0.15} \text{(SU(3))}]^2.$$  
\[181\]

This bound is currently dominated by statistical uncertainties stemming from experiment and it will thus be getting stronger in the future by improved measurements, even without theoretical improvements.

5. Investigate purely penguin induced decays: an example for a decay that has no tree-level contribution is $B^0 \to \phi \phi$, which is governed by a $b \to sss$-quark level transition. Traditionally such decays are considered to be most sensitive to new physics effects. The decay $B^0 \to \phi \phi$ has contributions from an $u$, $c$- and $t$-penguin. Its amplitude reads

$$A_f(B^0 \to \phi \phi) = \frac{G_F}{\sqrt{2}} \left[ \lambda_u \sum_{i=1,2} C_i(Q^*_i)^T + \lambda_c \sum_{i=3}^6 C_i(Q^*_i)^T \right].$$  
\[182\]
Using again the unitarity of the CKM matrix, we can rewrite the amplitude in a form where only two different CKM structures are appearing.

\[
A_f = \frac{G_F \lambda_c}{\sqrt{2}} \left[ \sum_{i=1,2} C_i(Q_i)^P \left( \lambda_1 \sum_{i=1,2} C_i(Q_i)^P - \sum_{i=3}^6 C_i(Q_i)^T \right) \right] + \frac{\lambda_a}{\lambda_c} \left[ \sum_{i=1,2} C_i(Q_i)^P \left( \lambda_1 \sum_{i=1,2} C_i(Q_i)^P - \sum_{i=3}^6 C_i(Q_i)^T \right) \right] \quad (183)
\]

Neglecting the second term, proportional to \(\lambda_a/\lambda_c\) we get the same result as in the case of the golden mode \(B_s^0 \to J/\psi\phi\): the measured mixing phase is \(\phi_s = -2\beta_s\). In the case of \(B_s^0 \to \phi\phi\) this might, however, not be a very good approximation. Our leading term is now given by the difference of the charm penguins and the top penguins, which will give a small contribution compared to the large tree-level term in the case of \(B_s^0 \to J/\psi\phi\). The sub-leading term is suppressed by \(\lambda_a/\lambda_c\), which is a small number, but the hadronic part is now the difference of up penguins and top penguins, which is of a similar size as leading term. Thus deviations of the measured phase in \(B_s^0 \to \phi\phi\) from \(-2\beta_s\) might tell us something about unexpected non-perturbative enhancements of the u-quark penguins compared to the c-quark penguins. More advanced theory investigations can be found in [Bartsch et al., 2008] [Beneke et al., 2007] [Cheng and Chua, 2009] [Datta et al., 2012]. First measurements (see [Aaij et al., 2014]) have still a sizable uncertainty, but they show no significant deviation of the mixing phase in \(B_s^0 \to \phi\phi\) from \(-2\beta_s\).

6. Try to do a calculation from first principles. Very recently penguin effects were estimated in that manner by [Frings et al., 2015] by proofing the infrared safety of the penguin contributions in a factorisation approach. This study suggests that penguin contributions to \(\phi_s\) in the case of \(B_s \to J/\psi\phi\) should be smaller than about 1°. First steps in such a direction have been performed by [Boos et al., 2004] and they were pioneered by [Bander et al., 1979]. In the framework of pQCD this was attempted recently by [Liu et al., 2014].

Most of the current investigations point toward a maximal size of SM penguin effects of about \(\pm 1°\), which is unfortunately very close to the current experimental precision of about \(\pm 2°\). Thus more theoretical work has to be done in that direction. Note that the LHCb constraint from the study of the decay \(B_s^0 \to J/\psi\phi\) [Aaij et al., 2015] gives a limit on penguin effects at about 1°.

B. Experiment

The experimental study of the \(CP\)-violating phase \(\phi_s\) has been pursued vigorously and fast experimental progress has been achieved. The main channels used are \(B_s^0 \to J/\psi h^+ h^-\), where the \(h^+ h^-\) system in general may comprise many states with different angular momenta. Many studies focus on the “golden mode,” \(B_s^0 \to J/\psi\phi\), discussed in Section II.B, which also contains the references to the latest experimental results. The analysis of this final state provides the constraint on both \(\Delta \Gamma_s\) and \(\phi_s\) and is therefore presented as a two-dimensional confidence level contour.

The determination of \(\phi_s\) requires the \(CP\)-even and \(CP\)-odd components to be disentangled by analysing the differential distribution \(d\Gamma/dtd\Omega\), where \(\Omega \equiv (\cos\theta_h, \cos\theta_\mu, \chi\), defined as (a) \(\theta_h\) is the angle between the \(h^+\) direction in the \(h^+ h^-\) rest frame with respect to the direction of the \(h^+ h^-\) pair in the \(B_s^0\) rest frame, (b) \(\theta_\mu\) is the angle between the \(\mu^+\) direction in the \(J/\psi\) frame with respect to the \(J/\psi\) direction in the \(B_s^0\) rest frame, and (c) \(\chi\) is the angle between the \(J/\psi\) and the \(h^+ h^-\), as shown in Fig. 18.

FIG. 18 Definition of the helicity angles. For details see text. The plot is taken from [Zhang and Stone, 2013]. In this figure the angle \(\theta_\mu\) is denoted as \(\theta_1\).

The decay \(B_s^0 \to J/\psi K^+ K^-\) proceeds predominantly via \(B_s^0 \to J/\psi\phi\) with the \(\phi\) meson decaying subsequently to \(K^+ K^-\). In this case the \(B_s^0\) decays to two vector particles, and the \(K^+ K^-\) pair is in a P-wave configuration. The final state is then the superposition of \(CP\)-even and \(CP\)-odd states, depending upon the relative orbital angular momentum of the \(J/\psi\) and the \(\phi\). The same final state can be produced also with \(K^+ K^-\) pairs in an S-wave configuration, as pointed out by Stone and Zhang [Stone and Zhang, 2009]. This S-wave component is \(CP\)-odd.

The decay width can be expressed in terms of four time-dependent complex amplitudes \(A_i(t)\). Three of them arise from the P-wave configuration, and, correspond to the relative orientation of the linear polarisation vectors of the \(J/\psi\) and \(\phi\) mesons, \((0, \perp, ||)\) (see [Aaij et al., 2015]), and one of them corresponds to the S-wave configuration. The distributions of decay angles and time for a \(B_s^0\) meson produced at time \(t = 0\) can be expressed in terms of ten terms, corresponding to the four polarisation amplitudes and their interference terms. The expressions for the decay rate \(d\Gamma(B_s^0)/dt d\Omega\) is invariant under
TABLE VI Values of the principal physics parameters determined from the LHCb polarisation-independent analysis of $B_s^0 \to J/\psi \phi$ in (Aaij et al., 2015b).

$$(\phi_s, \Delta \Gamma_s, \delta_0, \delta_{||}, \delta_{\perp}, \delta_S) \to (\pi - \phi_s, -\Delta \Gamma_s, -\delta_0, \delta - \delta_{||}, -\delta_{\perp}, -\delta_S).$$

Thus in principle there is a two-fold ambiguity in the results. This is removed by performing fits in bins of $m_{hh}$, see (Xie et al., 2009). Thus the LHCb collaboration performs the fit to the distribution $dn/dt d\Omega$ in bins of $m_{hh}$ to resolve this ambiguity. The projections of the decay time and angular distributions obtained from the analysis of the 3 $fb^{-1}$ LHCb data set is shown in Fig. 19 and the corresponding fit parameters are summarised in Table VI. Note that the mixing parameter $\Delta M_s$ is not constrained from other measurements in this fit and is consistent with world averages.

This decay mode has been studied also in the general purpose detectors at Tevatron (Aaltonen et al., 2012; Abazov et al., 2012a) and LHC (Aad et al., 2014; Khachatryan, 2015). The analysis method is similar to the one described before. Fig. 20 shows the fit projections obtained with the recent CMS measurements reported in Ref. (Khachatryan, 2015).

Another channel (see Stone and Zhang, 2009) was recognised to provide complementary information on $\phi_s$, namely $B_s^0 \to J/\psi f_0$, with $f_0 \to \pi^+\pi^-$. The original appeal of this mode is that it was assumed to be predominantly an $S$-wave decay, and thus not in need of the complex multidimensional fit just described. The study of the Dalitz plot of $B_s^0 \to J/\psi \pi^+\pi^-$ (Aaij et al., 2012a, 2014) revealed a more complex resonant structure. A combination of five resonant states are required to described the data (see Aaij et al., 2014): $f_0(980)$, $f_0(1500)$, $f_0(1790)$, $f_0(1270)$, and $f_2^{'+}(1525)$. The data are compatible with no additional non-resonant (NR) component, as well as a combination of these 5 resonances plus significant NR component, with a fit frac-
The combination of all measurements of $\phi_s$ performed by HFAG (Amhis et al. 2014) gives

$$\phi_s = (-0.034 \pm 0.033) \text{ rad},$$  \hspace{1cm} (185)

$$= (-1.95 \pm 1.89)^{\circ}.  \hspace{1cm} (186)$$

The results of different experiments are summarised in Table VII and in Fig. 22. It is remarkable that the achieved world average experimental uncertainty in $\phi_s$ is of the same level as the central value of the SM prediction given in Eqs. (159)–(160).
The average value of $\phi_s$ is consistent with the Standard Model, but there is still the possibility that subtle effects produced by diagrams mediated by new particles may be uncovered. The level or precision required to improve upon current status requires the consideration of effects neglected so far, such as the penguin contributions described above. Thus experiments have started to investigate decays that may constrain such contributions. The first such measurement is the study of the decay $B_0^+ \to J/\psi K^+$. This mode has both penguin and tree diagrams shown in Fig. 17. Theoretical models predict that in this case the penguin diagram is greatly enhanced with respect to the decay $B^0 \to J/\psi K$. The two decays $B^0 \to J/\psi \rho$ and $B^0_\rho \to J/\psi \phi$ are related by SU(3) symmetry if we also assume that the difference between the $\phi$ being mostly a singlet state, and the $\rho$ an octet state causes negligible breaking. If we assume equality between the penguin amplitudes and the strong phases in the two decay and neglecting higher order diagrams (see (Aaij et al., 2015e), LHCb finds the penguin phase to be $\delta^{\text{penguin}} = (0.05 \pm 0.56)\pi = 0.9 \pm 9.8$ mrad. At 95% CL, the penguin contribution in the $B^0 \to J/\psi$ decay is within the interval $(-1.05, +1.18)$. Relaxing these assumptions changes the limits on the possible penguin induced shift. Figure 23 shows how $\delta^{\text{penguin}}$ varies as a function of the difference in strong phases between the two decays, $\theta - \theta'$, indicating that the 95% CL limit on penguin pollution can increase to at most 1.2°. The phase $\delta^{\text{penguin}}$ is proportional to the ratio between penguin amplitudes $a/a'$. As this ratio varies over the interval 0.5 to 1.5, the limit on the penguin shift spans the range (±0.9, ±1.8), even allowing for maximal breaking between $\theta$ and $\theta'$. 

![FIG. 22](image-url) 68% CL regions in $B^0$ width difference $\Delta \Gamma_s$ and weak phase $\phi_s$ obtained from individual and combined CDF, D0, ATLAS, CMS, and LHCb likelihoods of $B^0 \to J/\psi \phi$, $B^0_\rho \to J/\psi K^+$, and $B^0_\rho \to J/\psi \phi$. The expectation within the Standard Model is shown as the black rectangle. The figure is taken from Ref. (Aaij et al., 2014).

![FIG. 23](image-url) Contours corresponding to 68% (dashed) and 95% (solid) confidence levels for ndf of two, respectively, for the penguin amplitude parameters $a/a'$. The figure is taken from Ref. (Aaij et al., 2015e).

A complementary approach is based on the study of the polarisation-dependent decay amplitudes of the decay $B^0 \to J/\psi K^+ \phi$ (Aaij et al., 2015d). The results of Ref. (Aaij et al., 2015e) and Ref. (Aaij et al., 2015d)

A LHCb combination of $J/\psi K^+ K^-$ (Aaij et al., 2015h) and $J/\psi \pi^+ \pi^-$ (Aaij et al., 2014b).

**TABLE VII** Measurements of the mixing phase $\phi_s$ in different $b \to c\bar{c}s$ channels, like $B^0 \to J/\psi \phi$, $B^0_\rho \to J/\psi K^+$, $B^0_\rho \to J/\psi \pi^+ \pi^-$, $B^0_\rho \to J/\psi h^+ h^-$ and $B^0_\rho \to D^+_s D^-_s$. The Standard Model expectation (neglecting penguins) for the phase $\phi_s$ reads $-0.0366 \pm 0.0020$. 

![FIG. 24](image-url)
FIG. 24 Limits on the penguin parameters $\alpha_i$ and $\theta_i$ obtained from intersecting contours derived from the CP asymmetries and branching fraction information in $B^0_s \to J/\psi K \pi^0$ and $B^0 \to J/\psi K^*$. Superimposed are the confidence level contours obtained from a $\chi^2$ fit to the data. The longitudinal (top), parallel (middle) and perpendicular (bottom) polarisations are shown. This figure is taken from Ref. [Aaij et al., 2015d].

are combined to produce the limits on penguin pollution shown in Fig. 24. Finally, the decay $B^0_s \to \phi\phi$ is analogous to $B^0_s \to J/\psi\phi$, but is forbidden at tree level. It proceeds mostly via the $b \to ss\bar{s}$ penguin, thus providing an excellent probe for the manifestation of interference of new physics particles with the penguin loop. The study of CP violation in this decay by LHCb ([Aaij et al., 2013a]) performs an unbinned maximum likelihood fit to $d\Gamma/(dt d\cos \theta_1 d\cos \theta_2 d\Phi)$, where $t$ is the decay time and $\theta_{1,2}$ is the angle between the $K^+$ track momentum in the $\phi_{1,2}$ meson rest frame and the $\phi_{1,2}$ meson parent momentum in the $B^0_s$ rest frame, and $\Phi$ is the angle between the two $\phi$ decay planes. The background is taken into account by assigning a weight to each candidate derived with an sPlot technique (see [Pivk and Le Diberder, 2005]) using the invariant mass of the four $K$ system as a discriminating variable. The fit results are shown in Fig. 25. The CP-violating phase is found to be in the interval $[-2.46, -0.76]$ rad at 68% confidence level. The $p$-value of the SM prediction is 16%. The precision of the $\phi_s$ determination is dominated by the statistical uncertainty and is expected to improve with more data. The current results are based on a sample of 1 fb$^{-1}$.

FIG. 25 One-dimensional projections of the $B^0_s \to \phi\phi$ fit for: (a) decay-time, (b) helicity angle $\phi$, (c) and (d) cosines of the helicity-angles $\theta_1$ and $\theta_2$ respectively. The data are represented as points, with the one-dimensional fit projections overlaid. The solid blue line shows the total signal contribution, which is composed of CP-even (long-dashed red), CP-odd (short-dashed green) and S-wave (dotted-blue) contributions. The figure is taken from Ref. [Aaij et al., 2013a].
V. CP VIOLATION IN DECAYS AND DIRECT MEASUREMENTS OF $\gamma$

A. Theory

CP violation in decays, also called direct CP violation, can arise if we have $|A_f| \neq |\bar{A}_f|$. In that case we expect the following CP asymmetry

$$ A_{\text{dir,CP},f}(t) = \frac{\Gamma(\bar{B}_s^0(t) \rightarrow \bar{f}) - \Gamma(B_s^0(t) \rightarrow f)}{\Gamma(\bar{B}_s^0(t) \rightarrow \bar{f}) + \Gamma(B_s^0(t) \rightarrow f)}, \quad (187) $$

to give a non-vanishing value. Inserting the time evolution for the decay rates from Eq. (21) and Eq. (37), we get a complicated expression, that vanishes, however for $|A_f| = |ar{A}_f|$, $|\bar{A}_f| = |A_f|$ and neglecting terms of order $\alpha_s$. Neglecting mixing in a first step, i.e. setting $\Delta M_s$ and $\Delta \Gamma_s$ equal to zero, we get the simplified expression

$$ A_{\text{dir,CP},f}(t) = \frac{|\bar{A}_f|^2 - |A_f|^2}{|\bar{A}_f|^2 + |A_f|^2}. \quad (188) $$

Using the definitions in Eq. (166) and in Eqs. (167,168) we can write the two amplitudes as

$$ A_f = |A_f^{\text{Tree}}| |A_f^{\text{Peng}}| e^{i[\phi_{\text{Peng}}^{\text{QCD}} + \arg(\lambda_f)]} + |A_f^{\text{Peng}}| e^{i[\phi_{\text{Peng}}^{\text{QCD}} + \arg(\lambda_f)]}, \quad (189) $$

$$ \bar{A}_f = |A_f^{\text{Tree}}| e^{i[\phi_{\text{Tree}}^{\text{QCD}} - \arg(\lambda_f)]} + |A_f^{\text{Peng}}| e^{i[\phi_{\text{Peng}}^{\text{QCD}} - \arg(\lambda_f)]}, \quad (190) $$

and we find for $A_{\text{dir,CP},f}(t)$ the following expression

$$ A_{\text{dir,CP},f}(t) = \frac{2|A_f^{\text{Tree}}||A_f^{\text{Peng}}| \sin \left( \phi_{\text{Peng}}^{\text{QCD}} - \phi_{\text{Tree}}^{\text{QCD}} \right) \sin [\arg(\lambda_f) - \arg(\lambda_{\bar{f}})]}{\left| |A_f^{\text{Tree}}|^2 + |A_f^{\text{Peng}}|^2 + 2|A_f^{\text{Tree}}||A_f^{\text{Peng}}| \cos \left( \phi_{\text{Peng}}^{\text{QCD}} - \phi_{\text{Tree}}^{\text{QCD}} \right) \cos [\arg(\lambda_f) - \arg(\lambda_{\bar{f}})] \right|} = \frac{2|r| \sin \left( \phi_{\text{Peng}}^{\text{QCD}} - \phi_{\text{Tree}}^{\text{QCD}} \right) \sin [\arg(\lambda_f) - \arg(\lambda_{\bar{f}})]}{1 + |r|^2 - 2|r| \cos \left( \phi_{\text{Peng}}^{\text{QCD}} - \phi_{\text{Tree}}^{\text{QCD}} \right) \cos \arg(\lambda_f) - \arg(\lambda_{\bar{f}})}, \quad (191) $$

where $|r|$ gives the modulus of the ratios of the penguin amplitude and the tree amplitude, analogous to Eq. (172). This simplified formula, that holds only in the absence of mixing, shows that we can have a direct CP violation in decay only, if we have at least two different CKM contributions with different weak and different strong phases. The size of the CP asymmetry is also proportional to the modulus of the penguin contributions normalised to the tree contributions. Thus such a asymmetry could in principle, e.g. arise in the decays $B_s^0 \rightarrow K^-\pi^+$ and $B_s^0 \rightarrow K^+\pi^-$ (see Fig. 16), where we expected large penguins. Using the definition of the CKM angle $\gamma$

$$ \gamma = \arg \left( \frac{-V_{us}V_{ub}^*}{V_{cd}V_{cb}^*} \right), \quad (192) $$

we can write to a very good approximation

$$ A_{\text{dir,CP},f}(t) = \frac{2|r| \sin \left( \phi_{\text{Peng}}^{\text{QCD}} - \phi_{\text{Tree}}^{\text{QCD}} \right) \sin \gamma}{1 + |r|^2 - 2|r| \cos \left( \phi_{\text{Peng}}^{\text{QCD}} - \phi_{\text{Tree}}^{\text{QCD}} \right) \cos \gamma}, \quad (193) $$

If $|r|$ and the strong phases would be known, this direct CP asymmetry could be used to determine the CKM angle $\gamma$. We already pointed out several times the difficulty of determining these hadronic parameters from a first principle calculation. Further strategies to determine $\gamma$ will be discussed below. On the other hand, using a measured value of $\gamma$, the direct CP asymmetry can give indications about the size of hadronic parameters, which is a very useful input in the investigation of penguin pollution.

Another possibility in the search for direct CP violation is the investigation of final states, that are common to $B_s^0$ and $\bar{B}_s^0$, as e.g. in $B_s^0 \rightarrow J/\psi \phi$ or $B_s^0 \rightarrow K^+K^-$. According to the definition of the asymmetry in Eq. (141) the coefficient of $\cos(\Delta M_s^0t)$ will be proportional to $A_{\text{dir}}$, which describes direct CP violation and which is non-zero if $|\lambda_f| \neq 1$. Here again the ratio $r$ will be the crucial parameter.

Finally one should also mention that $B_s^0$ decays can also be used to get some information about the CKM phase $\gamma$, which was defined above. This phase is directly proportional to the amount of CP violation in the SM. Thus any measurement of $\gamma$ is a measurement of CP violation.

In the case of the tree-level decay $B_s^0 \rightarrow D_s^{\pm}K^\mp$ the extraction of $\gamma$ was e.g. discussed in [Aleksan et al., 1992, 1993; DeBruyn et al., 2013; Dunietz and Sachs, 1998; Fleischer, 2003; Fleischer and Ricciardi, 2011; Gligorov, 2011]. $B_s^0 \rightarrow D_s^{\pm}K^\mp$ proceeds via a colour-allowed $b \rightarrow u c s$-transition and $B_s^0 \rightarrow D_s^- K^+$ proceeds via a colour-allowed $b \rightarrow c u s$-transition, see Fig. 26.
one expects that both amplitudes have a similar size, while the phase difference is given by the CKM element $\gamma$, which is more or less the phase of the CKM element $V_{ub}$. From the diagrams in Fig. 26 one sees that both the $B_s^0$ and $B_s^0$-meson can decay into the same final state. Thus an interference between mixing and decay can arise, and in the end the value of $\phi_s + \gamma$ can be extracted from measuring CP asymmetries. Such an extraction of $\gamma$ became very popular, using $B^- \to DK^-$, because tree-level decays are supposed not to be affected by new physics effects. In view of the increasing experimental precision this assumption should, however, be challenged. A recent study ([Brod et al., 2015]) found that current experimental bounds on different flavour observables that are dominated by tree-level effects, allow beyond SM effects to be as large as about $\pm 0.1$ in the tree-level Wilson coefficients $C_1$ and $C_2$. A new physics contribution to the imaginary part of $C_1$ of about 0.1 would modify the extraction of $\gamma$ from tree-level decays by about $4^\circ$ ([Brod et al., 2015]), which is smaller than the current experimental uncertainty of $\gamma$ (about $10^\circ$), but larger than the expected future uncertainty (about $1^\circ$). Here clearly more studies are necessary in order to constrain the possible space for new physics effects in tree level decays. Currently $B^0 \to D^{\pm} \overline{K} \mp$ decays lead to value of $\gamma = 115^{+28}_{-43}^\circ$ (see [Aaij et al., 2014d]), which is not competitive. An extraction of this angle from $B^0 \to \pi^+ \pi^-$, $B^0 \to K^+K^-$ and $B_{d,s} \to \pi\mp K^\mp$ decays, which have also loop contributions was e.g. discussed in [Ciuchini et al., 2012] [Fleischer 1999e, 2007a] [Fleischer and Knegjen, 2011b]. Assuming the SM value for $\beta_s$ and neglecting Standard Model penguins one gets a very precise value of $\gamma = 63.5^{+7.2}_{-5.7}^\circ$ (see [Aaij et al., 2013b]). For this decay the usual argument about the theoretical cleanliness of the extraction does, however, not hold. Finally [Bhattacharya and London 2015] discussed also the extraction of the CKM angle $\gamma$ from three-body decays $B^0, B_s^0 \to K_S h^+ h^-$ with $(h = K, \pi)$.

### B. Experiment

The discovery of CP violation in charmless two-body decays of $B^0$ and $B^+$ mesons by the BaBar and Belle experiments provide very interesting data, whose impact is difficult to ascertain in view of the challenges in determining precisely the hadronic matrix element relating the observed asymmetries with fundamental phases. The first observables of interests are the direct CP asymmetries. So far flavor SU(3) symmetry has been used to provide at least a theoretical framework to related such asymmetries measured in different decays. First principle calculations of the hadronic matrix elements involved will enable to fully exploit these measurements to test SM predictions. The study of direct CP asymmetries in $B_s^0$ decays provides valuable additional constraints.

The LHCb collaboration has measured CP violation asymmetries in $B_s^0 \to K^- \pi^+$ ([Aaij et al., 2012b]) and $B_s^0 \to K^+K^-$ ([Aaij et al., 2013b]). These measurements share the same level of complexity as the measurements of asymmetries mediated by the interference between $B_s^0 - B_s^0$ mixing and CP violation in direct decays: they require a determination of the flavor of the decaying $B_s^0$, a time-dependent analysis to disentangle $A_{CP}$ from the $B_s^0$ production asymmetry, in addition to a careful determination of all the instrumental asymmetries discussed before. An important advantage that enables the LHCb experiment to perform these measurements with high precision is the excellent hadron identification efficiency and purity provided by the ring imaging Cherenkov (RICH) detectors (see [Adinolfi et al., 2013]).

As an illustration, Fig. 27 shows the invariant mass spectra for different species of $B \to hh$ final states. There is excellent separation between different particle species.

Using the formalism of Ref. [Aaij et al., 2013d], the CP asymmetry is related to the raw asymmetry through

$$A_{CP} = A_{raw} - A_\Delta$$

(194)
with

$$A_\Delta(B_0^0 \to K^+\pi^-) = -A_D(K^+\pi^-) + \kappa_s A_P(B_0^0)$$  \hspace{1cm} (195)$$

where $A_D$ represents the detection efficiency asymmetry, that is derived from raw asymmetries measured for decays with known $A_{CP}$, $\kappa_s = -0.033 \pm 0.003(\text{s})$, and $A_P$ is the $B_0^0 - \bar{B}_0^0$ production asymmetry, derived from a fit to the time-dependent measured asymmetry. $A_P$ introduced an oscillatory component that makes it possible to measure the production asymmetry unambiguously. (More prolific $B_0^0$ decays are used here.) Note that $A_P$ has a very marginal effect on $A_{CP}$ because the fast flavor oscillations greatly diminish the correlation between the flavor at decay time with the flavor at production time. The final result is $A_{CP}(B_0^0 \to K^-\pi^+) = 0.27\pm0.04\pm0.01$ where the first error is statistical and the second systematic.

The study of the CP asymmetry and branching fraction of the decay $B_0^0 \to K^+\pi^-\bar{K}^+\pi^-$, combined with the knowledge of the corresponding observables in $B_0^0 \to \pi^+\pi^-$ can in principle be used to determine the CKM angle $\gamma \equiv \arg(-V_{ub}V_{ub}^*/V_{cd}V_{cd}^*)$ or $-2\beta_s$, if U-spin be a valid symmetry of the strong interaction. The LHCb collaboration, using their measurements of $CPV$ observables in $B_0^0 \to K^+\pi^-$, performs two analyses to determine either $\gamma$ or $\beta_s$ [Aaij et al. 2015b]. Here we quote the first analysis, that uses the measured value of $\beta_s$ (and neglecting Standard Model penguins) to derive

$$\gamma = (63.5^{+7.2}_{-6.7})^\circ.$$  \hspace{1cm} (196)$$

This value is consistent with the $\gamma$ value derived from tree-level decays. Further understanding of U-spin symmetry breaking as well as penguin pollution is needed to assess the impact of this measurement.

The decay $B_0^0 \to D_sK^-$ is sensitive to the angle $\gamma \equiv \arg(-V_{ub}V_{ub}^*/V_{cd}V_{cd}^*)$ of the Cabibbo-Kobayashi-Maskawa matrix. This is an example of determination of $\gamma$ from a tree-level process, and thus, in principle, not sensitive to effects induced by most new-physics models currently considered. Other such determinations of $\gamma$ from tree-level mediated processes have been performed at the $B$-factories and LHCb, through the study of $B^0 \to D^-\pi^+$, and $B^0 \to D^-K^+$ decays. In these decays, the ratio $r_D(\gamma) \equiv |A(B^0 \to D(\pm)\pi^+)/B^0 \to D(\pm)^+\pi^-|/|A(B^0 \to D(\pm)^+\pi^-)|$ is small, $r_D(\gamma) \approx 0.02$, while in the case of $B_s^0 \to D_s^+K^-$ the interfering amplitudes are of the same order of magnitude. Moreover, the decay width difference in the $B_s^0$ system, $\Delta\Gamma_s$, is non-zero, which allows a determination of $\gamma - 2\beta_s$ from the sinusoidal and hyperbolic terms in the decay time evolution, up to a two-fold ambiguity.

The measurement is sensitive to the combination $\gamma - 2\beta_s$, and, as we have seen that $\beta_s$ is now measured with great precision from the study of $B_s^0 \to J/\psi h^+h^-$, if Standard Model penguins are neglected, it can be directly translated into a measurement of $\gamma$. This decay has been studied by the LHCb collaboration using 1 fb$^{-1}$ of data and the measurement requires a fit to the decay-time distribution of the selected $B_s^0 \to D_s^+K^-$ candidates. It is a very challenging measurement because it requires the determination of the time-dependent efficiency, as well as the determination of the flavor of the decaying $B_s$. The kinematically similar mode $B_0^0 \to D^-\pi^+$ helps in constraining the time-dependent efficiency and the flavor tagging performance. In order to derive the CP-violating parameters, two different approaches have been pursued: the first, labelled sfit (see [Kid 2009]), consists of a statistical method to subtract background in maximum likelihood fit, without relying on any separate sideband or simulation for background modelling, whereas the second, labelled cfit separates signal from background by fitting for these two components with separate PDFs.

![Figure 27](image-url)

**Figure 27**: Panels (a) and (b) show the invariant mass spectra obtained using the event selection adopted for the best sensitivity to $A_{CP}(B_0^0 \to K^+\pi^-)$; panels (c) and (d) show the invariant mass spectra obtained using the event selection adopted for the best sensitivity to $A_{CP}(B_0^0 \to K^+\pi^-)$. Panels (a) and (c) show the $K^+\pi^-$ invariant mass, while panels (b) and (d) the $K^-\pi^+$ invariant mass. The plot is taken from [Aaij et al. 2015d].

The study of $B^0_s$ decays into two vector particles ($B^0_s \to V_1 V_2$), with the vector particles decaying into two pseudo-scalar mesons, has three helicity states that are allowed by angular momentum conservation, with amplitudes identified as $H_{+1}$, $H_{-1}$ and $H_0$. It is convenient to map these amplitudes in terms of three transversity states to be considered, identified as “longitudinal” ($0 \parallel$), “perpendicular” ($\perp$), and “parallel” ($\parallel$). They are related as

\begin{align}
A_0 &= H_0 \\
A_\perp &= \frac{H_{+1} - H_{-1}}{\sqrt{2}} \\
A_\parallel &= \frac{H_{+1} + H_{-1}}{\sqrt{2}}
\end{align}

Two such decays have been studied at LHCb: $B^0_s \to \phi\phi$ (discussed in the previous section), and $B^0_s \to K^{*0}K^{*0}$.

The study of the CP asymmetries and polarisation fractions in $B^0_s \to K^{*0}K^{*0}$ (see [Aaij et al., 2015]) takes a somewhat different approach. In view of the limited statistics, rather than trying to implement a flavor tagged time-dependent analysis, a study of the triple product and direct CP violation asymmetries is performed with a time-integrated analysis of $B^0_s \to K^{*0}K^{*0}$, without determining the flavor of the decaying $B^0_s$. In B mesons decays there are two possible triple products

\begin{align}
T_1 &= (\hat{n}_{V_1} \times \hat{n}_{V_2}) \cdot \hat{p}_{V_1} = \sin \phi \\
T_2 &= 2(\hat{n}_{V_1} \cdot \hat{n}_{V_2})(\hat{n}_{V_1} \times \hat{n}_{V_2}) \cdot \hat{p}_{V_1} = \sin 2\phi
\end{align}

They are found to be compatible with the Standard Model.

VI. MODEL INDEPENDENT CONSTRAINTS ON NEW PHYSICS

Indirect searches for new physics effects can be performed by assuming certain extensions of the SM and calculating then the contribution of this model to different flavour observables, e.g. $M_{12}^{s,NP}$. Combining these calculations with the SM contributions (e.g. $M_{12}^{s,SM}$) one gets a theory prediction for flavour observables that depends on unknown parameters $x, y, ...$ of the considered new physics model. Currently a comparison of experimental numbers and these new theory predictions enables to bound the parameter space of new physics models, e.g.

\[
\Delta M_s^{\text{Exp}} = 2 \left| M_{12}^{s,NP}(x, y, ...) + M_{12}^{s,SM} \right| .
\]

In future, this program could lead to a discovery of new physics effects, provided there is a sufficient control over the theoretical uncertainties. But also if physics beyond the SM will be first found by direct detection of new particles, the above discussed investigations will be crucial in order to determine the flavour couplings of the new model. There is a huge literature determining contributions of specific new physics models to the observables discussed in this review, in particular $B^0_s$ mixing. We present here some examples, not an exhaustive list: super-symmetric contributions were discussed e.g. by [Altmannshofer and Carena, 2012] [Buras]
A sequential, chiral, perturbative fourth generation of fermions is already excluded by experiment, see e.g. [Buchkremer et al., 2013]. Djourat and Lenz, 2012; Eberhardt et al., 2012a,b; Kuhl et al., 2013. This exclusion holds, however, not for e.g. vector-like quarks or a combination of a fourth chiral family with an additional modification of the SM, see e.g. Lenz, 2013.

The correction factor $1/8|M_{12}^{s,SM}/M_{12}^{s}|^2 / |1/\Delta_s|^2 \sin \phi_{12}^s$ in Eq. (11) and Eq. (12) stays still small.

In order to minimise the risk of betting on the wrong model, we will discuss here a little more in detail the general modification of $M_{12}^s$ by an a priori arbitrary complex parameter $\Delta_s$, while $\Gamma_{12}^s$ is just given by the SM prediction.

$$M_{12}^s = M_{12}^{s,SM}|\Delta_s|e^{i\phi_s^s}, \quad (200)$$

$$\Gamma_{12}^s = \Gamma_{12}^{s,SM}. \quad (201)$$

Such a modification changes the mixing observables in the following way:

$$\Delta M_{12}^{s,Exp} = 2 \left| M_{12}^{s,SM} \right| \cdot |\Delta_s|, \quad (202)$$

$$\Delta \Gamma_{12}^s = 2 \left[ \Gamma_{12}^{s,SM} \cos \left( \phi_{12}^{s,SM} + \phi_s^s \right) \right], \quad (203)$$

$$\phi_{12}^{s,Exp} = \frac{\Gamma_{12}^{s,SM} \sin \left( \phi_{12}^{s,SM} + \phi_s^s \right)}{M_{12}^{s,SM}} \cdot |\Delta_s|. \quad (204)$$

Also the phases $\phi_{12}^s$ and $\phi_s^s$ will get new contributions

$$\phi_{12}^{s,Exp} = \phi_{12}^{s,SM} + \phi_s^s, \quad (205)$$

$$\phi_s^{Exp} = -2\beta_s + \phi_s^s. \quad (206)$$

A sequential, chiral, perturbative fourth generation of fermions is already excluded by experiment, see e.g. [Buchkremer et al., 2013; Djourat and Lenz, 2012; Eberhardt et al., 2012a,b; Kuhl et al., 2013]. This exclusion holds, however, not for e.g. vector-like quarks or a combination of a fourth chiral family with an additional modification of the SM, see e.g. Lenz, 2013.

Having only two parameters $C_{BP}$ and $\phi_{BP}$ for parameterising new physics effects in $B_d^0$ and $B_s^0$ mixing corresponds to making the same assumptions as above: no new physics effects in $\Gamma_{12}^s$ and neglecting penguins. Investigating all

$$\Delta_s = \frac{M_{12}^{s,NP}(x,y,...) + M_{12}^{s,SM}}{M_{12}^{s,SM}}. \quad (207)$$

General model-independent investigations, using the above introduced notation, were done e.g. in [Lenz et al., 2011, 2012; Lenz and Nierste, 2007] and [Charles et al., 2013, 2014]. Below we discuss different approaches. Early investigations actually pointed towards large deviations from the SM. Unfortunately more data brought the extracted value for $\Delta_s$ in perfect agreement with the SM. The most recent result of such a investigation is depicted in Fig. (24). For completeness we show also the result for the $B_d^0$-system. The constraint from the mass difference, Eq. (202), is denoted by the orange ring. The finite size of the ring is mostly due to the theory uncertainty of $\Delta M_d$. In the case of $B_s^0$ mesons we have two rings, due to two different values for the CKM parameters $\rho$ and $\eta$ in the CKM-fit. The purple region stems from the measurement of the phase $\phi_s^s$. According to Eq. (200) this constrains also $\phi_s^s$. Here one has to keep in mind that this assumes no sizable SM penguins and also no new physics penguins. The dark-grey area stems from the semi-leptonic asymmetries. Here we are currently limited by the experimemtal precision. All in all we find in both mixing systems a perfect agreement with the SM, but there is still some sizable space (of the order of 10% in $|\Delta_s|$ and several degrees in the phase $\phi_s^s$) for new physics effects in $B_d^0$ and $B_s^0$ mixing. It is entertaining and may be instructive - in the view of the currently discussed deviations of experiment and SM - to show the corresponding plots from 2010 (Lenz et al., 2011) in Fig. (30). Here a quite clear hint for new physics effects can be seen, actually in both mixing systems, which unfortunately vanished completely in the last years. Similar investigations had been performed by the UTfit group (see e.g. the web-update of [Bona et al., 2006a, 2008]. In their notation one has

$$C_{BP} e^{2i\phi_{BP}} = \Delta_s, \quad (208)$$

$$C_{BP} = |\Delta_s|, \quad (209)$$

$$\phi_{BP} = \frac{1}{2} \phi_s^s. \quad (210)$$
available mixing observables UFfit finds the following preferred parameter ranges

\[ C_{B_d} = 1.052 \pm 0.084 \], \quad (211)  \\
\[ \phi_{B_d} = 0.72^\circ \pm 2.06^\circ \]. \quad (212)

Again, everything seems to be perfectly consistent with the SM, while space for sizable new physics effects, i.e. of the order of 10% in \( C_{B_d} \) and of the order of a factor of 10 in the phase \( \phi_{B_d} \). The corresponding allowed parameter regions for the \( B^0 \)-system read

\[ C_{B^0} = 1.07 \pm 0.17 \], \quad (213)  \\
\[ \phi_{B^0} = -2.0^\circ \pm 3.2^\circ \], \quad (214)

yielding the same conclusions as in the \( B^0 \)-system.

Sometimes these bounds are transferred into bounds on a hypothetical new physics scale. (Charles et al., 2014) use the following notation for deviation of \( M_{12}^s \) from its SM value

\[ M_{12} = M_{12}^{SM} (1 + h_s e^{2i\sigma_s} ) , \]
\[ 1 + h_s e^{2i\sigma_s} = |\Delta_s| e^{i\phi_s} . \quad (215) \]

Assuming further the operator

\[ \frac{C_{ij}^2}{\Lambda^2} (\bar{q}_i L \gamma^\nu q_j L)^2 \]  

(216)

to describe the new physics contribution to \( B_s^0 \) mixing (i.e. \( i = s \) and \( j = b \)), they find

\[ h_s \approx \frac{C_{sb}^2}{\lambda_{sb}^2} \left( \frac{4.5 \text{ TeV}}{\Lambda} \right)^2 , \quad (217) \]
\[ \sigma_s = \arg (C_{sb} \lambda_{sb}^* ) . \quad (218) \]

Here \( C_{ij} \) denotes the size of the new physics couplings and \( \Lambda \) is the mass scale of new physics. Both of these parameters are a priori unknown, because new physics has not been detected yet and an investigation of current experimental bounds on \( B_s^0 \) mixing gives only information about the ratio \( C_{ij}^2/\Lambda^2 \), but not about the individual values of the couplings and of the scale. \( \lambda_{sb}^2 = V_{ts}^* V_{tb} \) denotes the CKM structure of the SM contribution to \( B_s^0 \) mixing.

To make some statements about the new physics scale additional assumptions have to be made. Assuming that the coefficients \( C_{sb} \) have the same size as the CKM couplings, i.e. \( C_{sb} = \lambda_{sb} \) (Charles et al., 2014) got a
new physics scale $\lambda$ of about 19 TeV. Assuming instead $C_{sb} = 1$ the new physics scale increases to roughly 500 TeV. In particular the second scale is far above the direct reach of LHC and thus $B^0$ mixing could in principle probe new physics scales that are far away from being accessible via direct measurements. On the other hand one should not forget that the assumption about the size of the coupling is in principle arbitrary. If the new physics couplings are very small then also the new physics scale that can be probed is very low.

In order to fulfill our final goal of unambiguously disentangling hypothetical new effects from mixing observables a strict control over uncertainties is mandatory. Also the assumptions made above, have to be challenged. First of all we have to include penguins, both from the SM as well as from new sources, this will modify the phase $\phi_s$ to

$$\phi_s = -2\beta_s + \phi_s^\Delta + \delta_{\text{Peng,SM}} + \delta_{\text{Peng,NP}}. \quad (219)$$

SM penguins are expected to contribute at most up to 1°, while new physics penguins are less constrained. General new physics effects in $M_{12}^s$ will be treated as above

$$M_{12}^s = M_{12}^{s,\text{SM}} |\Delta_s| e^{i\phi_{12}^s}. \quad (220)$$

In addition we will also allow new effects in $\Gamma_{12}^s$, encoded by the parameter $\Delta_s$

$$\Gamma_{12}^s = \Gamma_{12}^{s,\text{SM}} |\Delta_s| e^{-i\phi_{12}^s}, \quad (221)$$

resulting in a modified mixing phase $\phi_{12}^s$

$$\phi_{12}^s = \phi_{12}^{s,\text{SM}} + \phi_s^\Delta + \tilde{\phi}_s^\Delta. \quad (222)$$

New contributions to $\Gamma_{12}^s$ can be due to new penguins and/or new contributions to tree-level decays. For a long time new physics effects in tree-level decays were considered to be negligible. Due to the dramatically improved experimental precision, this possibility has, however, to be considered. Taking only experimental constraints into account and no bias from model building, first studies performed by (Bobeth et al. 2014), (Bobeth et al. 2015) and (Brod et al. 2015) find that the tree-level Wilson coefficients $C_1$ and $C_2$ can easily be affected by new effects of the order of 0.1. Such a deviation can sometimes have dramatic effects, e.g. a modification of the imaginary part of $C_1$ by about 0.1 would modify the extracted value of the CKM angle $\gamma$ by about 4°, see (Brod et al. 2015),
which is larger than the expected future experimental uncertainty. Thus these possibilities should be taken into account for quantitative studies about new physics effects in mixing. For a future disentangling of new effects in mixing, penguins and tree-level decays clearly more effects in mixing. For a future disentangling of new effects in mixing, penguins and tree-level decays clearly more certainty. Thus these possibilities should be taken into following way:

\[ \Delta M_s = 2 \left| M^s_{12}^{\text{SM}} \right| \cdot |\Delta s|, \quad (224) \]

\[ \Delta \Gamma_s = 2 \left| M^s_{12}^{\text{SM}} \right| \left[ \Delta \right] \cos \left( \phi^s_{12}^{\text{SM}} + \phi^s + \phi^s \right), \quad (225) \]

\[ a^s_{sl} = \frac{\left| M^s_{12}^{\text{SM}} \right| \left[ \Delta s \right]}{\left| M^s_{12}^{\text{SM}} \right| \left[ \Delta s \right]} \sin \left( \phi^s_{12}^{\text{SM}} + \phi^s + \phi^s \right), \quad (226) \]

First steps in that direction have been done in the analysis of \( (\text{Lenz et al., 2012}) \) where in the so-called Scenario IV new physics in \( \Gamma_{12}^s \) was introduced by the parameter \( \delta_s \).

\[ \delta_q = \frac{\Gamma_{12}^s}{\Gamma_{12}^s_{\text{SM}}}. \quad (227) \]

This parameter is related to mixing observables in the following way:

\[ \Re (\delta_s) = \frac{\Delta \Gamma_s}{\Delta \Gamma_{s}^{\text{SM}}}, \Im (\delta_s) = -\frac{a^s_{sl}}{\Delta \Gamma_{s}^{\text{SM}}}. \quad (228) \]

In 2012 the fit of \( (\text{Lenz et al., 2012}) \) seemed to prefer some deviations of \( \Im (\delta_s) \) and \( \Im (\delta_s) \), which were mostly triggered by a at that time commonly accepted - but incomplete - interpretation of the di-muon asymmetry. In future these model independent investigations should include new physics effects in \( M^s_{12} \), in \( \Gamma_{12}^s \) and in penguins. Doing the latter might also include a combination of \( \Delta B = 2 \) and \( \Delta B = 1 \) observables.

\[ a^s_{sl} \left( (\text{Abazov et al., 2012b, 2013, 2014}) \right). \]

The measured value of \( a^s_{sl} \) based on the study of \( B^0 \rightarrow D^0_{+} \mu^- \bar{\nu}_\mu \) is still contributing to the average with the LHCb result, based on one-third of the run 1 data. The Tevatron experiments also initiated the studies of other CP-violating phenomena, such as the mixing phase \( \phi_s \) in the \( B^0 \rightarrow D^0_{+} \mu^- \bar{\nu}_\mu \) decay, albeit with large uncertainties.

CP violation studies in the \( B^0 \)-system are being continued by the LHC experiments. The pioneering work of the Tevatron experiments is followed by a new level of precision allowed by high statistics, improved detector performance, and new analysis techniques.

The outstanding contribution to the study of CP violation in the \( B^0 \)-system comes from the LHCb experiment. They perform the most precise measurement of all types of CP violation (see \( (\text{Aaij et al., 2012b, 2014b, 2014c, 2015b}) \)), as well as that of \( \Delta M_s \) and \( \Delta \Gamma_s \) (\( (\text{Aaij et al., 2013b}) \)). They measure the CKM angle \( \gamma \) not only in \( B^0 \)-decays previously studied by the \( e^+e^- B \)-factories, but also in \( B^0 \)-decays both in tree-mediated processes, and in loop-mediated processes. Finally, direct CP violation has been observed in several channels.

The current data do not confirm CP violation in the \( B^0 \)-system in excess of the SM prediction, as it was originally hoped for. Still, some room for new physics manifestations remains. In CP violation in the interference of decays and mixing quantified by the angle \( \phi_s \), the experimental uncertainty is getting very close to the SM central value. In this respect, the emphasis on understanding small corrections such as penguin pollution is a field of active investigation in the theoretical and experimental community. The theory prediction for CP violation in mixing is still orders of magnitude smaller than the experimental uncertainty. The level of understanding of the SM expectations for mixing observables and CP violating phenomena in the \( B^0 \)-system is now very advanced. Experimental studies have not only proven the CKM-mechanism to be the primary source of quark-mixing and CP violation, but they have also confirmed the validity of theoretical approaches such as the HQE to an unprecedented accuracy.

The uncertainty of the theory prediction for the mass difference \( \Delta M_s \) is about \( \pm15\% \), thus allowing for new effects of the same order in this observable. To improve the accuracy in \( \Delta M_s \) further, precise lattice evaluations of bag parameters and decay constants are mandatory. In this respect an uncertainty of about \( \pm5\% \) seems to be achievable in the next years. The calculation of the width difference according the HQE seems on less solid theoretical grounds. The assumption of quark hadron duality was questioned many times, see e.g. \( (\text{Ligeti et al., 2010}) \) or the discussion by \( (\text{Lenz, 2011}) \), and deviations of more than \( 100\% \) were discussed. Such a failure of the HQE is now clearly ruled out. The measurement of the width difference \( \Delta \Gamma_s \) has shown that the HQE works also in the most challenging channel - \( b \rightarrow c \bar{c}s \)

13 Again, the correction factor \( 1/8|\Gamma_{12}^s/\Gamma_{12}^s_{\text{SM}}|^2 |\Delta s/\Delta s|^2 \sin \phi_{12} \) stays small.
- with an accuracy of at least 20%. For further independent tests of the precision of the HQE, lattice determinations of the matrix elements that arise in lifetime difference of different b hadrons, like $\tau(B^+)/\tau(B^0)$, $\tau(B^+_s)/\tau(B^0)$ and $\tau(\Lambda_b)/\tau(B^0)$ are urgently needed, see the detailed discussion in (Lenz, 2014). Here it might also be insightful to study the charm sector, in particular the ratio $\tau(D^+)/\tau(D_0)$ and $\tau(D^+_s)/\tau(D_0)$. To reduce the uncertainty of the theory prediction of $\Delta \Gamma_s$ a first non-perturbative determination of dimension 7 matrix elements is needed, i.e., the bag parameters $B_{R_0}, B_{R_2}, B_{R_4}, B_{R_5}$ and $B_{R_6}$. Currently, this parameters causes the biggest individual uncertainty. Next, more precise lattice values of the complete SUSY-basis of $\Delta B = 2$ four quark operators are needed. In parallel to these non-perturbative improvements, NNLO-QCD corrections have to be calculated (i.e. $\Gamma_{3}^{(2)}$ and $\Gamma_{4}^{(1)}$ in our notation). Having all these improvements at hand, a final accuracy of about 5% for the $\Delta \Gamma_s$ prediction might also be feasible in the next years.

The current experimental uncertainty on $a^s_{lt}$ is still about a factor of 250 larger than the tiny central value of the Standard Model expectations, thus still allowing plenty of room for new physics effects. Turning to indirect CP violation we find that the current experimental precision is coming close to SM central value and also to the intrinsic theoretical uncertainties due to penguin contributions. In principle the weak phase $\phi_s$ measured e.g. in $B^0_s \rightarrow J/\psi\phi$ is a similar null test as the semi-leptonic asymmetries. In practice the theory prediction of the latter one is much more robust than the one for $\phi_s$. To fully exploit the improving experimental precision extended studies of penguin effects and a quantification of them are mandatory.

All LHC collaborations expect to continue the data taking at least up to 2030. The LHCb collaboration is currently engaging in a detector upgrade that should increase its sensitivity by a factor of 10, with a combination of operating at higher instantaneous luminosity, and the implementation of a purely software based trigger system, which will have to process the full 30 MHz of inelastic collisions delivered by the LHC. The physics opportunities offered by such an upgrade has been quantified by (LHC, 2014) assuming a total integrated luminosity of 50 fb$^{-1}$ (phase I upgrade) are given. For a comparison we show also the current theory uncertainty of the Standard Model predictions. The theory error in $\phi_s$ holds only for neglecting penguins.

### VIII. ACKNOWLEDGEMENTS

A.L. would like to thank Christine Davies, Tomomi Ishikawa, Andreas Jüttner and James Simone for helpful information about lattice inputs, Gilberto Tetlalmatzi-Xolocotzi for creating the diagrams in Fig. 1 and Fig. 20 checking some of the numerics and proof-reading, Matthew Kirk for providing Fig. 3 and proof-reading, Lucy Budge, Jonathan Cullen and Xiu Liu for checking some of the numerical updates. M.A. would like to thank the US National Science Foundation for their support, and S. Stone and P. Koppenburg for useful discussions.

### Appendix A: Numerical input for theory predictions

In this appendix we list all input parameters that were used for our numerical updates of several Standard Model predictions. We start with listing some very well-known parameters in Table XI that are mostly taken from the PDG ((Olive et al., 2014)). Next we list in Table XI some not so well determined input parameters. For lattice values our standard reference is FLAG ((Aoki et al., 2014)). In the case of $B_S/B$ FLAG did not provide an average, so we took the values from (Becirevic et al., 2002), (Bouchard et al., 2011), (Carrasco et al., 2014) and (Dowdall et al., 2014) and did our own naive average. For $B_{R_0}$ we took the preliminary value that can be read off the plots given by (Dowdall et al., 2014). $B_{R_4}$ and $B_{R_5}$ can be deduced from (Becirevic et al., 2002), (Bouchard et al., 2011), (Carrasco et al., 2014) and (Dowdall et al., 2014). The operators $R_1$ and $R_4$ are denoted by $O_3$ and $O_5$ in

### TABLE IX Statistical sensitivity of the LHCb upgrade to key observables discussed in this paper. For each observables the projected sensitivity at the end of Run II and with a luminosity of 50 fb$^{-1}$ (phase I upgrade) are given. For a comparison we show also the current theory uncertainty of the Standard Model predictions. The theory error in $\phi_s$ holds only for neglecting penguins.
the lattice literature

\[ R_1 \equiv \frac{m_s}{m_b} s_4 , \quad \tilde{R}_1 \equiv \frac{m_s}{m_b} s_5 . \]  

(A1)

The Fermilab-MILC Collaboration ([Bouchard et al. 2011]) uses again an additional factor 4

\[ R_1 \equiv \frac{m_s}{m_b} 4s_4 , \quad \tilde{R}_1 \equiv \frac{m_s}{m_b} 4s_5 . \]  

(A2)

Moreover one has to be aware of different normalisation factors used in the definition of the matrix elements. In e.g. ([Beneke et al. 1996] and [Lenz and Nierste 2007])

\[ \langle R_1 \rangle = \frac{7}{3} \frac{m_s}{m_b} M_B^2 f_B^2 B_{R_1} , \]  

(A3)

\[ \langle \tilde{R}_1 \rangle = \frac{5}{3} \frac{m_s}{m_b} M_B^2 f_B^2 B_{\tilde{R}_1} , \]  

(A4)

was used. This definition ensures that in vacuum insertion approximation the bag parameters \( B_{R_1} \) and \( B_{\tilde{R}_1} \) have the same value. In the lattice literature different normalisation factors, compared to \( \frac{4}{3} \) and \( \frac{5}{3} \), are used. ([Becirevic et al. 2002] and [Carrasco et al. 2014]) have

\[ \langle R_1 \rangle = 2 \frac{m_s}{m_b} M_B^2 f_B^2 B'_1 , \]  

(A5)

\[ \langle \tilde{R}_1 \rangle = 2 \frac{m_s}{m_b} M_B^2 f_B^2 B'_5 , \]  

(A6)

while ([Bouchard et al. 2011] and [Dowdall et al. 2014]) use

\[ \langle R_1 \rangle = 2 \frac{m_s}{m_b} M_B^2 f_B^2 B_4 , \]  

(A7)

\[ \langle \tilde{R}_1 \rangle = 2 \frac{m_s}{m_b} M_B^2 f_B^2 B_5 . \]  

(A8)

For the top-quark mass we did not take the PDG value, but a first combination of TeVatron and LHC results, presented by [ATLAS and Collaborations 2014]. \( M_Z^{(5)} \) we derived from the NLO running of \( \alpha_s \) using \( \alpha_s(M_Z) \) and \( M_Z \) given above as an input. The values of the CKM-elements were taken from the web-update of the CKMfitter group ([Charles et al. 2005]), similar results are given by UTfit ([Bona et al. 2006b]). Here the value of \( V_{ub} \) is taken from the fit and not from either an inclusive or an exclusive determination. Finally we also present in Table XII a list of additional lattice determinations for \( f_B \sqrt{B} \) and \( B_S/B \), given by HQPCD (LATTICE 2014 update by [Dowdall et al. 2014]), ETMC ([Carrasco et al. 2014]), the LATTICE 2015 update from the Fermilab-MILC Collaboration ([Bouchard et al. 2011]) and the LATTICE 2015 update from RBC-UKQCD of [Aoki et al. 2015].

### Appendix B: Error budget of the theory predictions

In this appendix we compare the error budget or our new Standard Model predictions with the ones given in 2011 by [Lenz and Nierste 2011] and the ones given in 2006 by [Lenz and Nierste 2007].

The error budget for the updated Standard Model prediction of \( \Delta M^{SM}_b \) is given in Table XIII. For the mass difference we observe no improvement in accuracy compared to the 2011 prediction, because the by far dominant uncertainty (close to 14%) stems from \( f_B \sqrt{B} \) and here the inputs are more or less unchanged. This will change as soon as new lattice values will be available. The next important uncertainty is the accuracy of the CKM element \( V_{ub} \), which contributes about 5% to the error budget. If one gives up the assumption of the unitarity of

TABLE XI: List of less precisely known input parameters needed for an update of the theory prediction of different mixing observables.
the 3 times 3 CKM matrix, the uncertainty can go up considerably. The uncertainties due to the remaining parameters, play no important role. All in all we are left with an overall uncertainty of close to 15%, which has to be compared to the experimental uncertainty of about 1 per mille. This situation leaves currently some space for new physics contributions to the mass difference $\Delta M_s$. With future improvements on the non-perturbative parameters a theoretical uncertainty in the range of 5% till 10% is feasible.

Next we study the error budget of the decay rate difference $\Delta \Gamma_s$ in Table XIV. The uncertainty in the decay rate difference also did not change considerably compared to 2011. The dominant uncertainty is still the unknown bag parameter of the power suppressed operator $R_2$. This input did not improve since 2011. Here and in [Lenz and Nierste 2011] and [Lenz and Nierste 2007] we took the very conservative assumption of $B_{R_{2,3}} = 1 \pm 0.5$. If in future these parameters could be determined with an uncertainty of about $\pm 10\%$, then an overall uncertainty of less than $\pm 10\%$ in $\Delta \Gamma_s$ would become feasible. First steps in the direction of a non-perturbative determination of $B_{R_2}$ within the framework of QCD sum rules have been done by [Mannel et al. 2007, 2011]. There, however, only sub-leading contributions were determined. Thus a calculation of the leading (three-loop) contribution would be very desirable. The second largest uncertainty stems from $f_{B_s} \sqrt{B}$, whose value did also not improve since 2011. There are, however, several new (mostly preliminary) results on market - HQPCD (LATTICE 2014 update by [Dowdall et al. 2014]), ETMC ([Carrasco et al. 2014]), the LATTICE 2015 update from the Fermilab-MILC Collaboration ([Bouchard et al. 2011]) and the LATTICE 2015 update from RBC-UKQCD of [Aoki et al. 2015] - that seem to indicate that $f_{B_s} \sqrt{B}$ can be determined with an uncertainty as low as 5% in the near future. In most of these works not only the matrix element of $Q$, but also the full $\Delta B = 2$ operator basis is studied. This will provide improved values for the bag parameters $B_S$, $B_{S_1}$, $B_{R_1}$ and $B_{R_2}$, via Eq. (66). Number three in the error budget is the dependence on the renormalisation scale, here a calculation of NNLO-QCD corrections would be necessary to further reduce

</table>
the error. First steps of such an endeavour were done by [Asatryan et al., 2012]. The new important dependence is the CKM element $V_{cb}$, which leads currently to an uncertainty of about 5%.

In the ratio $\Delta \Gamma_s^{\text{SM}} / \Delta M_s^{\text{SM}}$, one of the dominant uncertainties, the dependence on $f_{B_s}$. $B$ is cancelling and we get for the error budget the values given in Table XV. For $\Delta \Gamma_s / \Delta M_s$, we see a tiny improvement in the theoretical precision compared to 2011. The dominant uncertainty is given by the unknown matrix element of the dimension 7 operator $R_2$, followed by the uncertainty due to the renormalisation scale dependence. The overall uncertainty is currently 17.3%, which is also the final theoretical uncertainty that can currently be achieved for $\Delta \Gamma_s$. Future investigations, i.e. non-perturbative determinations of the matrix element of $R_2$ and NNLO-QCD corrections might bring down this uncertainty to maybe 5%.

The error budget for the semi leptonic CP asymmetries is finally listed in Table XVI. Here we witness some sizable reduction of the theory error. This quantity does not depend on $f_{B_s} \sqrt{s}$ and has only a weak dependence on $R_2$, thus the two least known parameters in the mixing sector do not affect the semi-leptonic asymmetries. The increase in precision stems mostly from better known CKM elements in particular of $V_{cb}$, in comparison to 2011. Currently the dominant uncertainty stems from the renormalisation scale dependence followed by the dependence on $V_{ub}$. For a reduction of the overall theoretical uncertainty considerably below 10% a NNLO-QCD calculation is mandatory.

Finally we present in Table XVII also the theory errors for the observables in the $B^0$-sector.
