ABSTRACT

We present H-band spectra of the candidate counterparts of five ultraluminous X-ray sources (ULXs; two in NGC 925, two in NGC 4136 and Holmberg II X-1) obtained with Keck/MOSFIRE (Multi-Object Spectrometer for Infra-Red Exploration). The candidate counterparts of two ULXs (J022721+333500 in NGC 925 and J120922+295559 in NGC 4136) have spectra consistent with (M-type) red supergiants (RSGs). We obtained two epochs of spectroscopy of the candidate counterpart to J022721+333500, separated by 10 months, but discovered no radial velocity variations with a 2σ upper limit of 40 km s\(^{-1}\). If the RSG is the donor star of the ULX, the most likely options are that either the system is seen at low inclination (<40°) or the black hole mass is less than 100 M\(_{\odot}\) unless the orbital period is longer than 6 years, in which case the obtained limit is not constraining. The spectrum of the counterpart to J120922+295559 shows emission lines on top of its stellar spectrum, and the remaining three counterparts do not show absorption lines that can be associated with the atmosphere of a star; their spectra are instead dominated by emission lines. Those counterparts with RSG spectra may be used in the future to search for radial velocity variations, and, if those are present, determine dynamical constraints on the mass of the accretor.

1 INTRODUCTION

Ultraluminous X-ray sources (ULXs) are point-like, off-nuclear X-ray sources with a luminosity in the 0.3–10 keV band >10\(^{39}\) erg s\(^{-1}\) (see Feng & Soria 2011 for a review). This is higher than the Eddington luminosity of a 10 M\(_{\odot}\) black hole (BH), which raises the question how ULXs attain their high luminosities. The majority of (candidate) ULXs, with \(L_X < 10^{39}\) erg s\(^{-1}\), likely contain stellar mass BHs (\(M_{BH} \leq 20\) M\(_{\odot}\)) accreting at or above their Eddington limit (Middleton et al. 2015 and references therein), although some of these ULXs could still contain massive stellar (\(M_{BH} = 20–100\) M\(_{\odot}\)) or even intermediate-mass BHs (\(M_{BH} = 100–10^3\) M\(_{\odot}\); Colbert & Mushotzky 1999). The most luminous ULXs, with \(L_X > 10^{41}\) erg s\(^{-1}\) (referred to as hyperluminous X-ray sources), are hard to explain as stellar mass BHs, and are strong candidates to host BHs more massive than those found in X-ray binaries in our Galaxy (Strohmayer & Mushotzky 2003; Farrell et al. 2009; Casares & Jonker 2014; Pasham, Strohmayer & Mushotzky 2014).

To date, there are only two ULXs with mass estimates that do not depend on modelling of their X-ray spectra (Liu et al. 2013; Motch et al. 2014). In both cases, although the uncertainties on the masses are large, a stellar mass BH is favoured as the accretor. In addition, Bachetti et al. (2014) discovered X-ray pulsations from M82 X-2, proving that the accretor in that ULX is a neutron star.

Improved model-independent mass measurements of ULX accretors are necessary to prove that the so-called ‘ultraluminous state’ (Gladstone, Roberts & Done 2009) is indeed a sign of super-Eddington accretion on to stellar mass BHs, to see if neutron star accretors are common among ULXs, and to find out if some ULXs contain massive stellar or intermediate-mass BHs. Dynamical mass measurements would be the most reliable method. Through

phase-resolved spectroscopic observations, it may be possible to trace the radial velocity curve of the donor and measure the mass function, setting a lower limit on the mass of the compact object. In the optical regime, attempts to measure the mass function in this way have been hampered by the presence of bright accretion discs in these systems (Roberts et al. 2011; Liu, Orosz & Bregman 2012). However, some ULXs may have red supergiant (RSG) donor stars, and these can outshine the disc in the near-infrared (NIR) part of the spectrum (Copperwheat et al. 2005).

In Heida et al. (2014), we describe our systematic search for NIR counterparts to nearby ULXs. We discovered 11 candidate counterparts that could be RSG donor stars. NIR spectroscopy with the Very Large Telescope has shown that one of these candidate counterparts, to RX J004722.4–252051 in NGC 253, is indeed an M-type RSG, with a peculiar velocity suggestive of a massive stellar BH accretor (Heida et al. 2015). In this paper, we describe the results of our observations with the Keck telescope that yielded NIR spectra of five other ULX counterparts from the Heida et al. (2014) sample. Two of the ULXs are situated in NGC 925 and two in NGC 4136. The fifth ULX is Holmberg II X-1 (hereafter Ho II X-1). Three of these ULXs (J022727+333500 in NGC 925 and J120922+295551 and J120922+295559 in NGC 4136) have been observed to reach maximum X-ray luminosities of a few times 10^{39} erg s^{-1}; J022727+333443 in NGC 925 and Ho II X-1 are brighter, reaching X-ray luminosities of a few times 10^{40} erg s^{-1} (Liu & Bregman 2005; Grisé et al. 2010; Swartz et al. 2011). The goal of this campaign was to characterize the NIR counterparts. Hence, we initially obtained only one epoch of data per source. Based on these observations, we obtained a second epoch for one source in NGC 925, J022721+333500, to search for radial velocity shifts.

This paper is organized as follows: in Section 2 we describe the setup of our observations. Section 3 describes our data reduction and analysis. In Section 4, we present the results for the separate counterparts and in Section 5 we discuss our findings and conclude.

2 OBSERVATIONS

We obtained H-band spectra of five ULX counterparts with the Multi-Object Spectrometer for Infra-Red Exploration (MOSFIRE; McLean et al. 2010, 2012), mounted on the Keck I telescope on Mauna Kea.1 MOSFIRE has a field of view of 6.1 arcmin × 6.1 arcmin with a pixel scale of 0.18 arcsec and a robotic slit mask system with up to 46 slits. The data were taken on December 22, 2014 January 10 (programme ID C241M) and 2014 November 4 (programme ID C201M; all dates are in UT). We used slit masks with 0.7-arcsec-wide slits which give us, in combination with the H-band filter and the fixed MOSFIRE diffraction grating, a spectral resolution R ≈ 3000 and spectral coverage from ~14 500 to 18 000 Å. The seeing on all nights was >0.7 arcsec (~0.8–1.0 arcsec), so that the resolution is set by the slit width. The integration time per exposure was 119.3 s on all nights. On 2013 December 22 and 2014 January 10, we used an ABBA nodding pattern with a nod amplitude of 1.5 arcsec along the slit. On 2014 November 4, we used a different slit orientation than we did for the observations of NGC 925 in 2013 December and 2014 January (see also Fig. 1). The orientation used in the first observations was chosen to avoid other nearby objects – the new orientation was chosen to better separate the two components of the elongated counterpart of J022721+333500; however, the seeing was not good enough to distinguish the two components. As a result, there were multiple sources in the slit containing J022721+333500, so we used an ABBA nodding pattern with a larger nod amplitude (2.9 arcsec for the first 20 exposures and 3.4 arcsec for the remaining 71 exposures). The total exposure times are listed in Table 1. We observed telluric standard stars at similar airmass as the science targets before and after every series of exposures. No flux standards were observed. For every slit mask configuration, we obtained flats and arc spectra in the afternoon before the observing run.

3 DATA REDUCTION AND ANALYSIS

We reduce the data with the MOSFIRE Data Reduction Pipeline version 2014.03.14 (MOSFIRE-DRP; described in detail by Steidel et al. 2014). The pipeline handles the background subtraction and combines the separate exposures to produce a 2D, rectified and wavelength-calibrated spectrum for every slit. The wavelength calibration is done by fitting a polynomial to the night sky lines, using wavelengths in vacuum. The typical standard deviation of the residuals after fitting is 0.1 Å (~2 km s^{-1} at 1.65 μm). For every observing night and target, we split the science exposures into two groups of at most 1.5 h and reduce them separately.

We then use the STARRY program FIGARO to extract the spectra with the profile and optextract tasks (Horne 1986). In the 2014 November observation of J022721+333500, we extract spectra of three objects that are visible in the slit. To correct for telluric absorption, we use the IDL routine XTELLCOR_GENERAL (Vacca, Cushing & Rayner 2003). For the final analysis (characterization of the spectra and – if possible – cross-correlation with template spectra to measure radial velocities), we use Tom Marsh’s program MOLLY. We load the wavelength-calibrated spectra into MOLLY and first run the task hfix to calculate the heliocentric velocity. Because the spectra are not flux calibrated, we normalize them by fitting a third-order polynomial and dividing by it. This removes any systematic flux offsets.

---

1 The data will be publicly available 18 months after the observations in the Keck Observatory Archive (https://koa.ipac.caltech.edu).
et al. (2015) to obtain a more robust measure of the uncertainty on the template by fitting a parabola to the cross-correlation function at each pixel shift. We then compute the radial velocity difference between spectrum and template by cross-correlating the spectra with template spectra of a range of spectral types (that have been normalized in the same way as our science spectra). As templates we use model RSG spectra from Lancer et al. (2007), with solar abundances, a mass of $15 \, M_\odot$ and temperatures ranging from 2900 to 5000 K. In the spectra of J022721+333500 and J120922+295559, we mask the regions with high noise levels due to strong telluric emission lines. With xcor we apply shifts to the spectrum of $-10$ to $+30$ pixels, with steps of 1 pixel, and calculate the value of the cross-correlation function for each pixel shift. xcor then computes the radial velocity difference between spectrum and template by fitting a parabola to the cross-correlation function at the peak pixel and its two neighbouring pixels. We follow Heida et al. (2015) to obtain a more robust measure of the uncertainty on the radial velocity measurements: we use the MOLLY command boot to produce 1000 bootstrapped copies of the spectra, and use xcor to cross-correlate them with one of the model spectra (with $T_{\text{eff}} = 3500$ K). The resulting distribution of radial velocities is Gaussian. We fit a Gaussian curve to this distribution and adopt the centroid of this Gaussian as a robust estimate of the radial velocity. This is fully consistent with the location of source 3 and the centre of the slit of 0.5 arcsec on the sky. From this, we derive a best estimate of the offset between the location of source 3 and the centre of the slit of 0.5 arcsec ± 0.05 arcsec (see Fig. 1). This corresponds to $2.8 \pm 0.3$ pixels on the MOSFIRE detector, or a velocity offset of $85 \pm 10$ km s$^{-1}$. Because the seeing was comparable to the slit width, this value is an upper limit on the velocity offset. If we correct for this, we find a radial velocity $\geq 420 \pm 15$ km s$^{-1}$ for source 3. The radial velocities of sources 1 and 2 are in agreement with what is expected from the radial velocity field of NGC 925 (de Blok et al. 2008). This proves that the objects are located in NGC 925, confirming the absolute magnitude reported for source 2 in Heida et al. (2014). That absolute magnitude is such that even if source 2 consists of two equally bright sources, they are both RSGs. The radial velocity of source 3 is somewhat offset with respect to the local radial velocity, but that source is still most likely located in NGC 925. The highest values for the cross-correlation function for all sources are found when cross-correlating with the templates with the lowest temperatures, indicating that these NIR sources are probably M-type stars.

4 RESULTS

4.1 NGC 925: J022721+333500

In the NIR image of NGC 925 (see Fig. 1), the counterpart to J022721+333500 appears elongated. Due to the orientation of the slits that we used for the observations in 2013 December and 2014 January, only one object (source 2 in Fig. 1) is visible in those observations. In the 2014 November observations, we used a slit orientation to better separate the components of the counterpart, but the seeing was not good enough to resolve them. In these observations, spectra of three objects are visible. Source 2 (see Fig. 1) corresponds to the elongated counterpart. All three spectra (sources 1 to 3) show a continuum with many absorption lines from neutral metals. The CO bandheads at 1.62 and 1.66 µm are also detected, proving that the objects are all K- or M-type stars (see Fig. 2 for the spectrum of source 2). We find no evidence for velocity broadening of the absorption lines. This is fully consistent with what we expect for RSGs, which have rotational velocities of at most a few km s$^{-1}$, undetectable at MOSFIRE's resolution of $\sim 80$ km s$^{-1}$ in the H band. From the cross-correlation with template spectra, we find a radial velocity of $495 \pm 11$ km s$^{-1}$ for source 1. For source 2, we find a radial velocity of $506 \pm 9$ km s$^{-1}$ for the Dec. 2013/Jan. 2014 spectrum and $500 \pm 14$ km s$^{-1}$ for the Nov 2014 spectrum. For source 3, we find a radial velocity of $502 \pm 8$ km s$^{-1}$. This source is not centred on the slit, which causes an offset in the radial velocity. The sources are too faint to be visible in our through-slit alignment images. However, brighter stars selected to check the slit alignment were detected and we use the comparison of their locations on the through-slit image with that of the deep WHT/LIRIS image (Heida et al. 2014) to determine the actual location of the slit on the sky. From this, we derive a best estimate of the offset between the location of source 3 and the centre of the slit of 0.5 arcsec ± 0.05 arcsec (see Fig. 1). This corresponds to $2.8 \pm 0.3$ pixels on the MOSFIRE detector, or a velocity offset of $85 \pm 10$ km s$^{-1}$.

Table 1. Description of the Keck/MOSFIRE observations. Apparent and absolute H-band magnitudes from Heida et al. (2014) are also provided. The last column describes the features that are visible in the NIR spectrum.

4.2 NGC 925: J022727+333443

The counterpart to J022727+333443 shows no continuum emission at all. The spectrum is dominated by a single strong emission line due to [Fe II] with a rest wavelength of 1.644 µm. Many weaker emission lines are visible, due to [Fe II], H (Brackett lines), He I, He II and H$_2$. These are indicated in Fig. 3. We fitted Gaussian profiles to these emission lines to calculate the radial velocity of the

NIR spectroscopy of five ULX counterparts 773

Figure 2. The normalized spectra of NGC 925 J022721+333500 (source 2, from the Dec. 2013/Jan. 2014 observation, blue line) and a 3500 K model from Lançon et al. (2007, red line, shifted downwards by 0.5 for clarity). The spectrum of J022721+333500 has been shifted by $-506$ km s$^{-1}$ and has been interpolated over wavelength ranges that were strongly affected by noise from telluric emission lines (grey shaded areas). The ‘emission lines’ visible near some of these ranges are due to this noise. The dashed lines indicate the positions of absorption lines that are indicative of late-type stars – from short to long wavelength: Mg I triplet (1.574, 1.575, 1.577 $\mu$m), Si I (1.59 $\mu$m), CO bandhead (1.62 $\mu$m), CO bandhead (1.66 $\mu$m), Si I (1.67 $\mu$m), Al I triplet (1.672, 1.675, 1.676 $\mu$m), OH (1.69 $\mu$m) and Mg I (1.71 $\mu$m).

Figure 3. The MOSFIRE spectrum of NGC 925 J022727+333443. Error bars (in red) are plotted for every third data point. Dotted lines indicate positions of He lines, dashed lines indicate positions of [Fe II] lines, solid lines indicate the H Brackett series and dot–dashed lines indicate positions of H$_2$ lines. The vertical lines representing spectral transitions are redshifted by 540 km s$^{-1}$. The inset shows the full profile of the [Fe II] $\lambda$1.644 emission line.

counterpart. The [Fe II], hydrogen and helium lines are well fitted by a Gaussian, but the H$_2$ lines are asymmetric. The radial velocity of the lines is $540 \pm 2$ km s$^{-1}$, proving that the source is part of NGC 925 and not a foreground or background object.

4.3 Ho II X-1

Ho II X-1 is a well-studied nearby ULX. It is surrounded by a nebula powered by the X-ray source that was discovered in optical observations (e.g. Pakull & Mirioni 2002; Lehmann et al. 2005). Our NIR spectrum shows a weak continuum with emission lines, most notably the [Fe II] ($\lambda$1.644) line and the hydrogen Brackett lines (see Fig. 4). We do not significantly detect any absorption lines. The S/N in the continuum is $\sim$4, which is too low to detect absorption lines from an RSG if they would be present. From the positions of the emission lines, we calculate a radial velocity of $165 \pm 3$ km s$^{-1}$, consistent with the radial velocity of the galaxy and earlier observations of the nebula.

4.4 NGC 4136: J120922+295551

The spectrum of the counterpart of J120922+295551 resembles that of Ho II X-1, with a weak continuum and emission lines (see Fig. 5). The 2D spectrum shows spatially extended emission around the position of the ULX, with stronger Brackett emission lines further from the ULX. The radial velocity of the counterpart as measured from the shift of the [Fe II] line is $550 \pm 5$ km s$^{-1}$, proving that the source is located in NGC 4136. The continuum emission could be due to an RSG. The S/N in the continuum is $\sim$5, and the strongest absorption line in an RSG, the CO bandhead at 1.62 $\mu$m, lies in a
Figure 4. The normalized MOSFIRE spectrum of Ho II X-1. The spectrum has been interpolated over wavelength ranges that were strongly affected by noise from telluric emission lines (grey shaded areas). Error bars (in red) are plotted for every third data point. The dashed line indicates the [Fe II] (λ1.644) line and the solid lines indicate the positions of the hydrogen Brackett lines. The vertical lines representing spectral transitions are redshifted by 165 km s$^{-1}$.

Figure 5. Part of the normalized MOSFIRE spectrum of NGC 4136 J120922+295551. The spectrum has been interpolated over wavelength ranges that were strongly affected by noise from telluric emission lines (grey shaded areas). Error bars (in red) are plotted for every third data point. The dashed line indicates the [Fe II] (λ1.644) line and the solid lines indicate the positions of the hydrogen Brackett lines. The vertical lines representing spectral transitions are redshifted by 550 km s$^{-1}$.

region that is heavily affected by noise from telluric emission lines, precluding us from detecting this feature. Other RSG absorption lines would not be significant at this S/N.

4.5 NGC 4136: J120922+295559

The spectrum of J120922+295559 shows continuum emission with absorption lines due to neutral metals and CO, indicative of late-type stars (see Fig. 6). However, the strongest feature in the spectrum is the [Fe ii] (λ1.644) emission line (dash-dotted line), similar to J022727+333443 and J120922+295551. Weaker emission lines are visible at the positions of the hydrogen Brackett lines that are in regions uncontaminated by noise from telluric emission lines, most notably at the position of the Br (10–4) line at 1.74 μm. Visual inspection of the 2D spectrum reveals that the peak of the [Fe ii] emission is spatially offset by ~0.8 arcsec with respect to the continuum emission, corresponding to a distance of ~45 pc. The Br (10–4) line does not show this spatial offset.

In late-type stars, the CO bandhead at 1.62 μm is the strongest absorption feature. Unfortunately, in the J120922+295559 spectrum, this bandhead is redshifted into a region heavily contaminated by noise from telluric emission lines, precluding us from reliably detecting it. There is an absorption feature visible at the position of the CO bandhead at 1.66 μm, as well as at the positions of the Si i line at 1.59 μm, the Al i triplet (1.672, 1.675, 1.676 μm), the OH line at 1.69 μm and the Mg i line at 1.71 μm. The cross-correlation with model RSGs yields a radial velocity of 586 ± 22 km s$^{-1}$, consistent with the radial velocity of NGC 4136 at the location of the ULX (Fridman et al. 2005) and thus proving that the source is indeed located in that galaxy. The highest values for the cross-correlation function are achieved with the templates with temperatures of 2900–4000 K, pointing towards an M-type RSG. We find no evidence for rotational broadening of the absorption lines.

We measure the radial velocity offset of the emission lines by fitting Gaussian profiles to the [Fe ii] (λ1.644) and Br (10–4) lines while masking the parts of the spectrum that contain absorption.
lines. Fitting the two lines separately, we find that their radial velocities are consistent with being the same within the error bars. Fitting them simultaneously to reduce the uncertainty, we find a radial velocity of $570 \pm 4$ km s$^{-1}$, consistent with the velocity of the RSG.

5 DISCUSSION AND CONCLUSIONS

We obtained Keck/MOSFIRE H-band spectra of five ULX counterparts, two located in NGC 925, two in NGC 4136 and Ho II X-1. Two of these, J022721+333500 in NGC 925 and J120922+295559 in NGC 4136, are consistent with being M-type supergiants. The absorption lines in such spectra can in principle be used to measure the radial velocity curve of the counterpart and obtain a lower limit on the BH mass.

5.1 Emission line spectra

The emission lines in the spectra of J022727+333443, Ho II X-1, J120922+295559 and J120922+295559 can have several origins. They may originate in a nebula, or in the accretion disc – although the latter is ruled out for the [Fe II] line in J120922. They may originate in a nebula, or in the accretion disc – although the latter is ruled out for the [Fe II] line in J120922. Although the spectrum of J120922+295559 has been shifted by $-586$ km s$^{-1}$ and has been interpolated over wavelength ranges that were strongly affected by noise from telluric emission lines (grey shaded areas), the spectrum of J120922+295559 has been shifted by $-586$ km s$^{-1}$ and has been interpolated over wavelength ranges that were strongly affected by noise from telluric emission lines (grey shaded areas). Solid lines indicate the positions of hydrogen Brackett lines and dashed lines indicate the positions of absorption lines that are indicative of late-type stars – from short to long wavelength: Si $\lambda$ (1.59 $\mu$m), CO bandhead (1.62 $\mu$m), CO bandhead (1.66 $\mu$m), Si $\lambda$ (1.67 $\mu$m), Al $\lambda$ triplet (1.672, 1.675, 1.676 $\mu$m), OH (1.69 $\mu$m) and Mg $\lambda$ (1.71 $\mu$m). The dash–dotted lines indicate the position of the [Fe II] (1.644 $\mu$m) emission line, the peak of which lies at 4.7 (relative units).

Figure 6. The normalized spectra of NGC 4136 J120922+295559 (blue line, with error bars – in red – plotted at every third data point), and a 3500 K model from Lançon et al. (2007, red line, shifted downwards by 0.5 for clarity). The spectrum of J120922+295559 has been shifted by $-586$ km s$^{-1}$ and has been interpolated over wavelength ranges that were strongly affected by noise from telluric emission lines (grey shaded areas). Solid lines indicate the positions of hydrogen Brackett lines and dashed lines indicate the positions of absorption lines that are indicative of late-type stars – from short to long wavelength: Si $\lambda$ (1.59 $\mu$m), CO bandhead (1.62 $\mu$m), CO bandhead (1.66 $\mu$m), Si $\lambda$ (1.67 $\mu$m), Al $\lambda$ triplet (1.672, 1.675, 1.676 $\mu$m), OH (1.69 $\mu$m) and Mg $\lambda$ (1.71 $\mu$m). The dash–dotted lines indicate the position of the [Fe II] (1.644 $\mu$m) emission line, the peak of which lies at 4.7 (relative units).

The emission line spectra of NGC 4136 J120922+295559 (blue line, with error bars – in red – plotted at every third data point), and a 3500 K model from Lançon et al. (2007, red line, shifted downwards by 0.5 for clarity). The spectrum of J120922+295559 has been shifted by $-586$ km s$^{-1}$ and has been interpolated over wavelength ranges that were strongly affected by noise from telluric emission lines (grey shaded areas). Solid lines indicate the positions of hydrogen Brackett lines and dashed lines indicate the positions of absorption lines that are indicative of late-type stars – from short to long wavelength: Si $\lambda$ (1.59 $\mu$m), CO bandhead (1.62 $\mu$m), CO bandhead (1.66 $\mu$m), Si $\lambda$ (1.67 $\mu$m), Al $\lambda$ triplet (1.672, 1.675, 1.676 $\mu$m), OH (1.69 $\mu$m) and Mg $\lambda$ (1.71 $\mu$m). The dash–dotted lines indicate the position of the [Fe II] (1.644 $\mu$m) emission line, the peak of which lies at 4.7 (relative units).

The apparent and absolute magnitudes mentioned in Table 1 are those of the combined flux in the emission lines and the continuum emission. To estimate the magnitude of a possible donor star, we estimate the magnitude of the continuum. Because we did not observe a flux standard star to calibrate our spectra, we do this by comparing the S/N level for the continuum emission to values calculated with the MOSFIRE exposure time calculator$^2$ for our observing conditions and a range of magnitudes. We find that for Ho II X-1, the flux in the emission lines does not contribute significantly to the magnitude of the counterpart. For J022727+333443 in NGC 925, we find a limit on the apparent magnitude of $H \approx 22.5$, corresponding to an absolute magnitude $M_H \gtrsim -7$. This makes it unlikely that the donor star is a supergiant of spectral type F or later (Tokunaga 2000). For J120922+295559 in NGC 4136, we find an apparent magnitude of $H \approx 20.5$, corresponding to an absolute magnitude $M_H \approx -9.4$. If the continuum emission in this source is mainly due to the donor star, this absolute magnitude would mean it is still most likely an RSG. A deeper observation might then reveal stellar absorption lines.

5.2 RSG spectra

The RSG candidate counterpart of the ULX RX J004722.4−252051 in NGC 253 (Heida et al. 2015) shows a radial velocity that is offset with respect to its environment by $66 \pm 6$ km s$^{-1}$. The candidate donor stars of J022721+333500 and J120922+295559

$^2$ http://www2.keck.hawaii.edu/inst/mosfire/etc.html
The probability that the radial velocities measured in our two spectra of NGC 925 J022721+333500 obtained 10 months apart are consistent within 40 km s$^{-1}$, as a function of BH mass and orbital period, for system inclinations of 20°, 40° and 60° (left to right). We assume a mass of 10 M$_{\odot}$ for the RSG and that mass transfer happens through Roche lobe overflow. Orbital periods shorter than 3 years are ruled out given the radius of an M-type RSG. The step-like shape is due to the discrete sampling of BH masses.

Figure 7. The probability that the radial velocities measured in our two spectra of NGC 925 J022721+333500 obtained 10 months apart are consistent within 40 km s$^{-1}$, as a function of BH mass and orbital period, for system inclinations of 20°, 40° and 60° (left to right). We assume a mass of 10 M$_{\odot}$ for the RSG and that mass transfer happens through Roche lobe overflow. Orbital periods shorter than 3 years are ruled out given the radius of an M-type RSG. The step-like shape is due to the discrete sampling of BH masses.

ACKNOWLEDGEMENTS

MH would like to thank Nick Konidaris for his help with the MOSFIRE DRP. We thank Tom Marsh for developing MOLLY. TPR acknowledges support from STFC as part of the consolidated grant award ST/L00075X/1. The work of DJW and DS was carried out at University of Durham on June 2, 2016.
