ABSTRACT

We present predictions for the clustering of galaxies selected by their emission at far-infrared (FIR) and sub-millimetre wavelengths. This includes the first predictions for the effect of clustering biases induced by the coarse angular resolution of single-dish telescopes at these wavelengths. We combine a new version of the GALFORM model of galaxy formation with a self-consistent model for calculating the absorption and re-emission of radiation by interstellar dust. Model galaxies selected at 850 μm reside in dark matter haloes of mass \( M_{\text{halo}} \sim 10^{11.5} \) – \( 10^{12} h^{-1} M_\odot \), independent of redshift (for \( 0.2 \lesssim z \lesssim 4 \)) or flux (for \( 0.25 \lesssim S_{850 \mu m} \lesssim 4 \) mJy). At \( z \sim 2.5 \), the brightest galaxies (\( S_{850 \mu m} > 4 \) mJy) exhibit a correlation length of \( r_0 = 5.5^{+0.3}_{-0.2} h^{-1} \) Mpc, consistent with observations. We show that these galaxies have descendants with stellar masses \( M_* \sim 10^{11} h^{-1} M_\odot \) occupying haloes spanning a broad range in mass \( M_{\text{halo}} \sim 10^{12} – 10^{14} h^{-1} M_\odot \). The FIR emissivity at shorter wavelengths (250, 350 and 500 μm) is also dominated by galaxies in the halo mass range \( M_{\text{halo}} \sim 10^{11.5} – 10^{12} h^{-1} M_\odot \), again independent of redshift (for \( 0.5 \lesssim z \lesssim 5 \)). We compare our predictions for the angular power spectrum of cosmic infrared background anisotropies at these wavelengths with observations, finding agreement to within a factor of \( \sim 2 \) over all scales and wavelengths, an improvement over earlier versions of the model. Simulating images at 850 μm, we show that confusion effects boost the measured angular correlation function on all scales by a factor of \( \sim 4 \). This has important consequences, potentially leading to inferred halo masses being overestimated by an order of magnitude.

Key words: galaxies: evolution – galaxies: formation – galaxies: high-redshift – large-scale structure of Universe – submillimetre: diffuse background – submillimetre: galaxies.

1 INTRODUCTION

The emission from galaxies formed throughout cosmic history appears as a diffuse cosmological background. The far-infrared (FIR) and sub-millimetre (sub-mm, 100 μm–1 mm) part of this background [Cosmic Infrared Background (CIB); e.g. Puget et al. 1996; Fixsen et al. 1998] is mostly produced by the re-emission of stellar radiation by interstellar dust, with a small (\( \lesssim 5 \) per cent) contribution from dust heated by UV/X-ray emission from AGN (e.g. Almaini, Lawrence & Boyle 1999; Silva, Maiolino & Granato 2004), and has a similar energy density to the background at UV/optical wavelengths (e.g. Hauser & Dwek 2001; Dole et al. 2006). This implies that most of the star formation over the history of the Universe has been obscured by dust. Understanding the nature of the galaxies that contribute to the CIB is therefore critical to a full understanding of galaxy formation.

Much progress has been made in recent years to map the sky at these long wavelengths either from space, using satellites such as the Herschel Space Observatory (Pilbratt et al. 2010), its predecessor the Balloon-borne Large Aperture Sub-Millimetre Telescope (Devlin et al. 2009), and the Planck satellite,1 or from ground-based instruments, such as the Super Common User Bolometer Array 2 (SCUBA-2; Holland et al. 2013). However, one of the key problems with observations at these long wavelengths is confusion noise, caused by the coarse angular resolution (\( \sim 20 \) arcsec full width at half-maximum (FWHM)) of the telescopes and the high surface density of detectable objects. This means that only the brightest objects can be resolved above the confusion background from imaging at these wavelengths.

Whilst these individually resolved galaxies do not form the dominant contribution to the CIB (e.g. Oliver et al. 2010), they are important to study in their own right as they appear to be amongst the most highly star-forming objects in the Universe, as their FIR/sub-mm emission is thought to be powered by star formation, leading to inferred star formation rates (SFRs) of \( \gtrsim 100 M_\odot \text{yr}^{-1} \) (e.g. Smail et al. 2002; Michałowski, Hjorth & Watson 2010; Swinbank et al. 2014). However, the use of gravitational lensing (e.g. Smail, Ivison & Blain 1997; Knudsen, van der Werf & Kneib 2008; 1 http://www.esa.int/Planck

*E-mail: w.i.cowley@durham.ac.uk
Chen et al. (2013), stacking techniques (e.g. Béthermin et al. 2012; Geach et al. 2013) and interferometers (e.g. Hatsukade et al. 2013; Carniani et al. 2015) has to some extent circumvented the problem of confusion noise and allowed up to ~80 per cent of the CIB to be statistically resolved into galaxies.

Placing these FIR/sub-mm galaxies into a consistent evolutionary context has proven challenging. In terms of resolved sub-mm galaxies (SMGs), it is still unclear what physical mechanism triggers the prodigious SFRs inferred from observations. In the Local Universe (z < 0.3), the majority of ultraluminous galaxies (LIR > 10^{12} L_{\odot}) are gas-rich major mergers (e.g. Sanders & Mirabel 1996), but whether this is the dominant triggering mechanism at the peak of the SMG redshift distribution (z ~ 2.5; e.g. Chapman et al. 2005; Simpson et al. 2014) is unclear. Some dynamical studies using emission lines from the 12CO molecule (e.g. Tacconi et al. 2008) and Hα (e.g. Menéndez-Delmestre et al. 2013) have concluded that they see evidence of merger activity, though the sample sizes are small (<10 objects). The merger scenario is also supported by some recent morphological studies (e.g. Chen et al. 2015). However, examples of rotationally supported discs have also been found (e.g. Swinbank et al. 2011) suggesting that the star formation was triggered by secular disc instabilities. Simulations suggest that the contraction of gas towards the centre of a galaxy, fuelling the star formation which results in the enhanced FIR/sub-mm emission (e.g. Mihos & Hernquist 1996; Chakrabarti et al. 2008; Narayanan et al. 2010), could also cause accretion on to a supermassive black hole (SMBH), with the resulting quasar phase quenching the star formation (e.g. Di Matteo, Springel & Hernquist 2005), possibly resulting in compact quiescent galaxies (e.g. Toft et al. 2014). It has been speculated that SMGs could then evolve on to the scaling relations observed for massive local elliptical galaxies, based on simple arguments involving the time-scale of the burst and the ageing of the stellar population (e.g. Lilly et al. 1999; Swinbank et al. 2006; Simpson et al. 2014), and assuming that most of the stellar mass at z = 0 is put in place during the ‘SMG phase’. However, González et al. (2011) present an alternative scenario in which SMGs evolve into galaxies with stellar mass ~10^{11} h^{-1} M_{\odot} at z = 0, with the SMG phase accounting for little of this stellar mass.

An important constraint on any evolutionary picture can come from observational measurements of the clustering of selected galaxies, which provides information on the masses of the dark matter haloes in which they reside. However, measuring the clustering of FIR/sub-mm galaxies has proven challenging. Some studies have failed to produce significant detections of clustering (e.g. Scott et al. 2002; Webb et al. 2003; Coppin et al. 2006; Williams et al. 2011), or the results derived from similar data have proven contradictory (e.g. Cooray et al. 2010; Maddox et al. 2010). Nevertheless, at 850 μm Hickox et al. (2012) used a cross-correlation analysis (e.g. Blake et al. 2006) to find that SMGs selected from the LESS2 source catalogue (Weiße et al. 2009) have a correlation length of r_0 = 7.7^{+1.3}_{-2.3} h^{-1} Mpc. This result is consistent with an earlier study by Blain et al. (2004) who used a pair-counting analysis to show that SMGs selected from a number of SCUBA fields have a correlation length of 6.9 ± 2.1 h^{-1} Mpc. These correlation lengths are consistent with SMGs residing in haloes of mass 10^{12}–10^{13} h^{-1} M_{\odot}. Both the Hickox et al. and Blain et al. studies were performed prior to interferometric observations, which showed that many single-dish sources are in fact composed of multiple, fainter galaxies (e.g. Wang et al. 2011; Hodge et al. 2013). It is currently unclear from previous work how this result affects the observed clustering of SMGs. We therefore present predictions for this in Section 4.

Information about the clustering, and therefore host halo masses, of the unresolved FIR/sub-mm galaxies which contribute to the bulk of the CIB, can be obtained from the angular power spectrum of CIB anisotropies. The first attempts to measure this, by Peacock et al. (2000) for the Hubble Deep Field observed by SCUBA at 850 μm, and Lagache & Puget (2000) for a 0.25 deg^2 Infrared Space Observatory field at 170 μm, found at best only a tentative signal above the shot noise. More recently studies have been able to measure a clear signal (e.g. Viero et al. 2009; Amblard et al. 2011; Viero et al. 2013; Planck Collaboration XXX 2014), though significant modelling is required in order to interpret these results in terms of halo masses. The Viero et al. (2013) and Planck Collaboration studies infer the typical halo mass for galaxies that dominate the CIB power spectrum as 10^{11.95 ± 0.5} h^{-1} M_{\odot} and 10^{12.43 ± 0.1} h^{-1} M_{\odot}, respectively, making various assumptions such as the form of the relationship between galaxy luminosity and halo mass being independent of redshift, and that this relationship is the same for both central and satellite galaxies.

Historically, hierarchical models of galaxy formation have struggled to simultaneously match the number density of FIR/sub-mm galaxies at high redshift (z > 2) and the present-day (z = 0) luminosity function in optical and near-infrared (near-IR) bands (e.g. Granato et al. 2000). It follows that theoretical predictions for the clustering, and host halo masses, of such galaxies are few. van Kampen et al. (2005) present a number of predictions for the angular clustering of SMGs under different scenarios. However, these models are phenomenological and do not attempt to predict the sub-mm flux of galaxies in a self-consistent manner. Baugh et al. (2005) presented a version of GAlFORM, the Durham semi-analytic model of hierarchical galaxy formation (Cole et al. 2000), which successfully reproduced the observed number counts and redshift distribution of SMGs at 850 μm as well as the z = 0 luminosity function in optical and near-IR bands. In order to do so these authors found it necessary to dramatically increase the importance of high-redshift galaxy mergers relative to earlier versions of GAlFORM (e.g. Cole et al. 2000; Benson et al. 2003) through the introduction of a top-heavy initial mass function (IMF) in starburst galaxies. In this instance sub-mm flux was calculated by combining GAlFORM with the radiative transfer code GRASIL (Silva et al. 1998). Predictions of the SMG clustering in this model were presented in Almeida, Baugh & Lacey (2011), who found a correlation length of 5.6 ± 0.9 h^{-1} Mpc for galaxies with S_{850μm} > 5 mJy at z = 2, in good agreement with the subsequent observational measurement of Hickox et al. (2012). The angular power spectrum of CIB anisotropies predicted by this model was presented in Kim et al. (2012) and was within a factor of ~3 of the measurements of the Planck Collaboration XVIII (2011).

Predictions for the clustering of FIR/sub-mm selected galaxies from hydrodynamical simulations of galaxy formation are limited due to the relatively small volumes that can (currently) be simulated using this method (~100 h^{-1} Mpc)^3 (e.g. Vogelsberger et al. 2014; Schaye et al. 2015) and the computational expense of the radiative transfer required to properly calculate the sub-mm fluxes of the simulated galaxies. Nevertheless, Davé et al. (2010) used a hydrodynamical simulation to argue that 850 μm SMGs at z = 2 should be a highly clustered population with a correlation length of r_0 ~ 10 h^{-1} Mpc and a bias of ~6. However, this work did not calculate the sub-mm flux for any of the simulated galaxies and instead relied entirely on the ansatz that SMGs are the most highly star-forming objects.
galaxies at a given epoch, with an SFR selection limit chosen such that the number density of the simulated sample matched that of observed SMGs.

Here we present predictions for the clustering, and host halo masses, of galaxies selected by total IR luminosity, and FIR/sub-mm emission. We use a new version of the GAlFORM semi-analytic model (Lacey et al. 2015, henceforth L15). This is combined with a simple model for the reprocessing of stellar radiation by dust in which the dust temperature is calculated self-consistently (as is done in e.g. González et al. 2011; Kim et al. 2012). This paper is structured as follows: in Section 2 we introduce the theoretical model, in Section 3 we present predictions for the spatial clustering of galaxies selected by their total IR luminosity (L_{IR}), and by their 850 μm flux, in Section 4 we make predictions for the angular clustering of simulated galaxies selected by their 850 μm flux, taking into account the effect of the single-dish beam used to make such observations, and in Section 5 we present predictions for the angular power spectrum of CIB anisotropies at 250, 350, and 500 μm. We conclude in Section 6.

2 THE THEORETICAL MODEL

Here we introduce our model, which combines a dark matter only N-body simulation, a state-of-the-art semi-analytic model of galaxy formation and a simple model for the reprocessing of stellar radiation by dust in which the dust temperature is calculated self-consistently based on radiative transfer and global energy balance arguments. We also briefly describe some of the physical properties of the dusty star-forming galaxies in this model.

2.1 GAlFORM

The Durham semi-analytic model of hierarchical galaxy formation, GAlFORM, was introduced in Cole et al. (2000), building on ideas outlined by White & Rees (1978), White & Frenk (1991) and Cole et al. (1994). Galaxy formation is modelled ab initio, beginning with a specified cosmology and a linear power spectrum of density fluctuations and ending with predicted galaxy properties at different redshifts.

Galaxies are assumed to form within dark matter haloes, with their subsequent evolution controlled in part by the merging history of the halo. These halo merger trees can be calculated using a Monte Carlo technique following the extended Press–Schechter formalism (e.g. Parkinson, Cole & Helly 2008), or extracted directly from a dark matter only N-body simulation (e.g. Helly et al. 2003; Jiang et al. 2014). For this work, we use halo merger trees derived from a Millennium-style dark matter only N-body simulation (Springel et al. 2005; Guo et al. 2013), but with cosmological parameters consistent with the 7-year Wilkinson Microwave Anisotropy Probe (WMAP7) results (Komatsu et al. 2011), henceforth referred to as MR7. This simulation has a volume of (500 h^{-1} Mpc)^3 and a minimum halo mass of 1.86 × 10^{10} h^{-1} M_{\odot}, slightly higher than the value for the original Millennium simulation (1.72 × 10^{10} h^{-1} M_{\odot}). Throughout this work we use the halo merger trees and halo masses as defined by the ‘Dhalo’ algorithm (Jiang et al. 2014).

Some studies have shown that including baryonic processes (e.g. AGN feedback) in N-body simulations can affect the matter power spectrum by ≲10 per cent for scales λ ≲ 5 h^{-1} Mpc at z = 0 when compared to that of the dark matter only counterpart, due to the redistribution of gas on these scales (e.g. van Daalen et al. 2011). We note that this effect is not modelled here. However, we are confident that our science results are robust to this as we are mostly concerned with the clustering of galaxies on larger scales.

In GAlFORM, the baryonic processes thought to be important for galaxy formation are included as a set of continuity equations which essentially track the exchange of mass between stellar, cold disc gas and hot halo gas components. The parameters in these equations are then calibrated against a broad range of data from both observations and simulations. Stellar population synthesis models (e.g. Bruzual & Charlot 2003; Maraston 2005) are used to calculate stellar luminosities. For a more detailed description of the semi-analytic method see the reviews of Baugh (2006) and Benson (2010).

Various GAlFORM models exist in the literature. For this work, we use a new model (L15) which incorporates a number of important physical processes from earlier models and can reproduce an unprecedented range of observational data. The physical processes modelled include a prescription for radio-mode AGN feedback (Bower et al. 2006) in which quasi-hydrostatic hot halo gas is prevented from cooling by energy input from relativistic jets, and an improved star formation law in galaxy discs based on an empirical relation between SFR and molecular gas (Blitz & Rosolowsky 2006) first implemented in GAlFORM by Lagos et al. (2011). There is also a mode of star formation which takes place in a galactic bulge, triggered by either a disc instability or a galaxy merger. Following such an event, the cold gas component in the galactic disc (formed through the cooling of hot halo gas) is transferred to a bulge/spheroid and a star formation law in which the SFR time-scale scales with the dynamical time of the bulge is used, until this gas is exhausted. This transfer of gas to the bulge also results in accretion on to a galaxy’s central SMBH. Throughout we use the term ‘starburst’ to refer to a galaxy undergoing bulge star formation, and ‘quiescent’ to mean one in which star formation occurs only in the disc. We note that these definitions do not necessarily align with, for example, those based on a galaxy’s position on the SFR–M* plane. This is discussed in more detail in a forthcoming work (Cowley et al. in preparation).

A feature of the L15 model important here is the inclusion of a top-heavy stellar IMF for star formation in bursts, which allows the model to reproduce the observed number counts of galaxies selected at a range of FIR/sub-mm wavelengths (250–1100 μm; Cowley et al. 2015; L15) though a much less extreme IMF slope is used here than was advocated in Baugh et al. (2005). A solar neighbourhood Kennicutt (1983) IMF is used in disc (quiescent) star formation.

We note that we do not vary any of the fiducial L15 model parameters for this work and as such the results presented here can be considered as true predictions of the model, as it was calibrated without considering any clustering data.

2.2 The dust emission model

To determine a simulated galaxy’s FIR/sub-mm flux, a model is required to calculate the absorption and re-emission of stellar radiation by interstellar dust. Here, a simple model is used which

---

3 Ω_0 = 0.272, Λ_0 = 0.728, h = 0.704, Ω_b = 0.0455, σ_8 = 0.81, n_s = 0.967.

4 For an IMF described by dx/d ln M_⋆ ∝ M_⋆^{-x}, x = 1 in L15 whereas x = 0 was used in Baugh et al. For reference, a Salpeter (1955) IMF is described by x = 1.35.
assumes dust exists in two components, each with its own temperature: (i) dense molecular clouds of uniform density in which stars are assumed to form and (ii) a diffuse interstellar medium smoothly distributed throughout a double exponential disc.

The energy of stellar radiation absorbed by each component is calculated by solving the equations of radiative transfer in this simple geometry. The dust emission is then calculated using global energy balance arguments, assuming the dust emits as a modified blackbody. Importantly this means that the dust temperature is not a free parameter, but is calculated self-consistently for each dust component in each galaxy. The model is therefore capable of making bona fide multiwavelength predictions without having to assume a shape for the spectral energy distribution (SED) of the dust emission.

Despite its simplicity, the model is able to accurately reproduce the predictions of the more sophisticated radiative transfer code GRASIL (Silva et al. 1998) for $\rho_{\text{rest}} \gtrsim 70 \mu m$, thus we are confident in its application to the wavelengths under investigation in this paper. For more details regarding the dust emission model, we refer the reader to Cowley et al. (2015) and the appendix of L15.

2.3 The nature of dusty star-forming galaxies in the L15 model

Here we give a brief description of the properties of the dusty star-forming galaxies which dominate the CIB and SMG population in the L15 model, in order to aid the reader in understanding results presented later.

Dusty star-forming galaxies are predicted to be predominantly starburst galaxies (i.e. star formation occurs within the bulge), with the starburst phase being triggered by secular disc instabilities. The importance of disc instabilities in the model is twofold: (i) they result in faster gas consumption at higher redshifts by triggering starbursts, and (ii) they are the dominant channel in the model for the growth of SMBHs which allow AGN feedback to suppress star formation in massive haloes ($M_{\text{halo}} \gtrsim 10^{12} h^{-1} M_\odot$) at late times. This means that the model displays the requisite star formation at early times to reproduce the redshift distribution of SMGs at $z \gtrsim 1$ without overestimating it at lower redshifts.

Dusty star-forming galaxies are mostly central galaxies in the model, instantaneous ram-pressure stripping of the hot gas halo is implemented when a galaxy becomes a satellite (its hot halo gas component is transferred to that of the parent halo) and it is assumed that no more gas will accrete on to the disc of the satellite galaxy. For this reason, the star formation in satellite galaxies is reduced due to their diminishing gas supply, and they form a minor proportion ($\lesssim 5$ per cent) of the dusty star-forming population.

Here we present some of the physical properties of the dusty star-forming galaxy population in the L15 model, the illustrative values presented are the median values for the $L_{\text{IR}} > 10^{12} h^{-2} L_\odot$ population at $z = 2.6$. Dusty star-forming galaxies are amongst the most massive galaxies in the simulation at a given epoch with stellar masses $M_\star \sim 2 \times 10^{10} h^{-1} M_\odot$ and they reside in dark matter haloes most conducive to star formation in the model ($M_{\text{sub}} \sim 10^{11.8} h^{-1} M_\odot$). They also have high SFRs $\sim 140 h^{-2} M_\odot$ yr$^{-1}$, translating to specific SFRs of $\sim 8$ Gyr$^{-1}$ (approximately $10 \times$ the sSFR of the model’s ‘main sequence’), dust to stellar mass ratios, $M_{\text{gas}}/M_\star \sim 0.03$ and molecular gas fractions $M_{\text{cold,mol}}/(M_{\text{cold,mol}} + M_\star) \sim 0.4$.

3 THE SPATIAL CLUSTERING OF DUSTY STAR-FORMING GALAXIES

In this section we present predictions for the spatial clustering of simulated galaxies selected by their total IR luminosity, $L_{\text{IR}}$, and their emission at 850 $\mu m$. We discuss how the clustering evolves with redshift, how this relates to the dark matter haloes the selected objects occupy, and how the populations selected by $L_{\text{IR}}$ and $S_{850\mu m}$ are related. We also briefly discuss the stellar and host halo mass of the $z = 0$ descendants of the 850 $\mu m$ selected galaxies.

We present the predictions of our model in this section without considering any observational effects, such as the angular resolution of the telescopes used to identify galaxies at sub-mm wavelengths, redshift-space distortions, the accuracy of observed redshifts or any selection biases such effects can introduce. Some of these issues are dealt with in Section 4.

3.1 The two-point spatial correlation function

We quantify the clustering of our selected galaxies by use of the two-point spatial correlation function $\xi(r)$, which is defined as the excess probability of finding two galaxies at a given separation $r > 0$, compared to a random distribution:

$$\delta P(r) = n^2[1 + \xi(r)] \delta V_1 \delta V_2,$$

(e.g. Peebles 1980), where $n$ is the mean number density of the selected galaxies at a given redshift and $\delta V_i$ is a volume element. The two-point correlation at $r = 0$ is described by a Dirac delta function $\delta^3(r)/n$ (referred to as the shot noise term) as the galaxies are treated as point objects.

On large scales, the correlation function is shaped by the clustering of galaxies in distinct dark matter haloes, referred to as the two-halo term (e.g. Berlind & Weinberg 2002; Cooray & Sheth 2002). On these scales the correlation functions of the dark matter and galaxies have a similar shape but differ in amplitude. This difference in amplitude, or bias, is defined as

$$b(r) = \left( \frac{\xi_{\text{gal}}(r)}{\xi_{DM}(r)} \right)^{1/2}.$$  

Although galaxy bias is scale dependent (e.g. Angulo et al. 2008) it is usually approximated as constant on large scales, where it is governed by a weighted average of the bias values over the haloes that are occupied. The effective bias of the selected galaxy population can then be written as

$$b_{\text{eff}} = \frac{\int b(M) n(M) \langle N_{\text{gal}}(M) \rangle dM}{\int n(M) \langle N_{\text{gal}}(M) \rangle dM},$$

where $b(M)$ is the bias of haloes with mass $M$, $n(M)$ is the halo mass function such that $n(M) dM$ describes the comoving number density of haloes in the mass range $[M,M + dM]$, and $\langle N_{\text{gal}}(M) \rangle$ is the mean of the halo occupation distribution (HOD, the expected number of selected galaxies within a halo of mass $M$).

We measure the correlation function in the simulation volume using the standard estimator (e.g. Peebles 1980):

$$\xi(r) = \frac{DD(r)}{N_{\text{gal}} n \Delta V(r)/2} - 1,$$

where DD$(r)$ is the number of distinct galaxy pairs with separations between $r \pm \Delta r/2$, $N_{\text{gal}}$ is the total number of selected galaxies, $n$ is their mean number density and $\Delta V(r)$ is the volume of the spherical shell between $r \pm \Delta r/2$. We make use of the periodic nature of our simulation to calculate this volume analytically.

We calculate errors using the volume bootstrap method advocated in Norberg et al. (2009). We divide our simulation volume into $N_{\text{sub}} = 27$ subvolumes and for each bootstrap realization draw $3N_{\text{sub}}$
subvolumes at random (with replacement). As our volume is no longer periodic due to the spatial sampling we calculate $\xi(r)$ for each bootstrap realization using the estimator presented in Landy & Szalay (1993):

$$\xi(r) = \frac{\text{DD}(r) - 2\text{DR}(r) + \text{RR}(r)}{\text{RR}(r)},$$

where $\text{DD}(r)$, $\text{DR}(r)$ and $\text{RR}(r)$ represent the number of data-data, data-random and random-random pairs with separations between $r \pm \Delta r/2$. For each bootstrap realization, we generate a random catalogue with 10 times more points than there are galaxies in our initial sample, normalizing the DR and RR terms in equation (5) to have the same total number of pairs as DD. We calculate 100 bootstrap realizations from which we derive the $1\sigma$ percentile variation for each bin of separation.

3.2 Spatial clustering evolution of IR luminous galaxies

Here we present predictions for the clustering of galaxies selected by their total IR luminosity $L_{\text{IR}}$, derived by calculating the energy of stellar radiation absorbed by dust through solving the equations of radiative transfer in our assumed dust geometry.

We show the model predicted spatial clustering for galaxies selected by their $L_{\text{IR}}$ in Fig. 1 at a selection of redshifts, $z \sim 0.5$, and luminosities, $L_{\text{IR}} \sim 10^{9.5} - 10^{13} h^{-2} L_{\odot}$. For clarity, we only show volume bootstrap errors for the most luminous (i.e. least numerous) population. We are confident that our selected galaxies are complete populations, at all redshifts considered here, and are not affected by the finite halo mass resolution of our simulation. We also plot the correlation function of the dark matter, calculated using a randomly chosen subset of $10^6$ dark matter particles from the MR7 simulation, and can see that the selected galaxy populations represent biased tracers of the underlying matter distribution. Note that we do not
show $\xi(r)$ of the most luminous population at $z < 1$ as the number of pairs of such objects in our simulation at these redshifts is not sufficient to provide a robust prediction.

It is notable that the clustering of the selected galaxies shows a dependence on the selection luminosity, and redshift. This is summarized in Fig. 2, which shows the redshift evolution of the comoving correlation length, $r_0$, defined such that $\xi(r_0) \equiv 1$, and the large-scale bias of the selected populations. In the right-hand panel of Fig. 2, we show for reference the large-scale bias evolution of haloes selected by a lower IR luminosity. At $z = 1.5$ this is no longer the case, as the most luminous population has a slightly lower median halo mass than the next most luminous. This breaks the monotonic relation of increasing bias with increasing luminosity seen at higher redshifts.

In Fig. 2 we also compare our predictions to the observational estimates of Dolley et al. (2014), who used FIR luminosities derived from 24 μm fluxes. We show the $r_0$ values for their redshift bins that are complete in IR luminosity, for clarity showing only most and least-luminous samples within each redshift bin. The colour scale indicates the mean IR luminosities of their samples, the bins for which have a width of 0.25 dex in $L_{IR}$. Whilst the overall agreement is generally favourable, Dolley et al. find, in contrast to our predictions, that for $z < 1$ at a fixed redshift $r_0$ increases with increasing luminosity. The model also appears to underpredict the clustering of $\sim 10^{11.5} h^{-2} L_\odot$ galaxies at $z \sim 1$ and overpredict the clustering of $\sim 10^{10.5} h^{-2} L_\odot$ galaxies at $z \sim 0.3$.

There could be a number of reasons for this discrepancy. Dolley et al. assumed a power-law slope of $\gamma = 1.9$ in order to derive a correlation length. If a lower value is used (as favoured by our model) they note that this increases their estimated correlation lengths (e.g. assuming $\gamma = 1.8$ gave correlation lengths $\sim 0.5 h^{-1}$ Mpc larger). Our model shows a variation of power-law slope with redshift and IR luminosity, with lower luminosity samples having generally flatter slopes. It is also unclear whether the simulated galaxies follow the relation used by Dolley et al. to derive $L_{IR}$ from the observed 24 μm photometry, which is based on templates derived from local galaxies (Rieke et al. 2009) and adjusted at higher redshifts according to Rujopakarn et al. (2013). Alternatively, further investigation into the physical processes which produce the distribution of galaxies on the SFR–$M_{\text{halo}}$ plane as predicted by the model (Fig. 3) is required to understand how the predicted clustering could be brought into better agreement with the Dolley et al. results.

Our predictions for correlation length in this section are lower than the observational estimates of Farrah et al. (2006), who infer
correlation lengths of 9.4 ± 2.2 and 14.4 ± 2.0 h⁻¹ Mpc for galaxies at $z \sim 1.7$ and 2.5, respectively, with $L_{IR} \gtrsim 5 \times 10^{11} h^{-2} L_{\odot}$. However, we do not consider this a significant discrepancy, due to the complicated selection criteria of the Farrah et al. sample, which we do not attempt to model here, and assumptions made by those authors regarding the redshift distribution of their sample, and their parametrization of $\xi(r, z)$.

3.3 Spatial clustering of SMGs

In this section we present the spatial clustering of galaxies selected by their 850 µm flux. We focus on this wavelength as it is historically the wavelength at which the majority of ground-based observations of FIR/sub-mm galaxies have been performed, due to the atmospheric transmission window. The real space two-point correlation function and large-scale bias for our selected galaxies are presented in Fig. 4 over a range of redshifts which span the peak of the redshift distribution of the selected SMGs.

We consider three samples of galaxies selected by flux: (i) a bright population with $S_{850\mu m} > 4$ mJy (median $L_{IR} \sim 10^{12.2} h^{-2} L_{\odot}$ at $z = 2.6$, green line) as this is a typical limit at which single-dish surveys can detect SMGs (e.g. Weiß et al. 2009, though note we do not consider the effects of the single-dish beam in this section), (ii) an intermediate population with $S_{850\mu m} > 1$ mJy (median $L_{IR} \sim 10^{11.8} h^{-2} L_{\odot}$ at $z = 2.6$, red line) as this is an approximate limit to which Atacama Large Millimetre/sub-millimetre Array (ALMA)-detected galaxies as part of Cycle 0 observations (e.g. Hodge et al. 2013) and (iii) a fainter population with $S_{850\mu m} > 0.25$ mJy (median $L_{IR} \sim 10^{11.2} h^{-2} L_{\odot}$ at $z = 2.6$, blue line) which are in principle detectable by ALMA, though with longer integration times and more antennas than were used in Cycle 0. Our selected galaxies exhibit clustering with $r_0 \sim 5 h^{-1}$ Mpc, with little dependence on flux, for the fluxes considered here.

3.3.1 SMG halo occupation distribution

We can gain further insight into the clustering of the selected SMGs from Fig. 5 which shows their halo mass probability distribution (i.e. the product of the halo mass function and the mean of the HOD $n(m)(N_{gal}|M)$ in equation 3, left-hand panels) and the mean of the HOD $(N_{gal}|M)$ in equation 3, right-hand panels) at redshifts $z = 3.1$ and 2.1 (top and bottom panels, respectively). It is evident from the left-hand panels that SMGs reside predominantly in haloes of mass $\sim 10^{11.5}$–$10^{12}$ $h^{-1} M_{\odot}$, the halo mass range most conducive for star formation in our model over a broad range of redshifts (see fig. 27 of L15). For example, at $z = 3.1$: 87, 74 and 54 per cent of galaxies in the $S_{850\mu m} > 4$, 1 and 0.25 mJy selected populations, respectively, reside in haloes within this mass range. At $z = 2.1$ these percentages are 75, 69 and 53 per cent, respectively. The halo mass at which the probability distribution peaks seems insensitive to the 850 µm flux of the galaxies and their redshift, although fainter galaxies do occupy a broader range of halo masses, and the distribution for satellite galaxies (dashed lines) peaks at a higher halo mass ($\sim 2 \times 10^{12} h^{-1} M_{\odot}$).

In the right-hand panels, the HODs for central galaxies (dotted lines) peak below unity for all samples. The HODs only reach unity for satellites in fainter samples in massive haloes ($M_h \gtrsim 10^{13} h^{-1} M_{\odot}$ at $z = 2.1$). Models which force $(\langle N_{SMGs,c}\rangle = 1$ and adopt the same number density of SMGs would place them in more massive haloes than predicted by our model. An $S_{850\mu m} > 1$ mJy galaxy is hosted in roughly 1 in every 10 haloes of $\sim 10^{12} h^{-1} M_{\odot}$, showing the need for a large number of halo histories to be sampled (i.e. large cosmological volumes simulated) in order to make robust predictions for the SMG population as a whole (see also e.g. Almeida et al. 2011; Miller et al. 2015).

We attribute the minima in the HODs for the central galaxies to merger-induced SMGs. In our model AGN feedback becomes effective in massive haloes ($M_{halo} \gtrsim 10^{12} h^{-1} M_{\odot}$), which prevents hot halo gas from cooling, limiting the fuel for star formation and

Figure 3. Predicted distribution of galaxies in the SFR − halo mass plane at $z = 4.2$ (top panels) and $z = 1.5$ (bottom panels). Left-hand panels: distribution of all galaxies with the shading representing the galaxy number density at that position on the plane, with red indicating the highest number densities and purple the lowest. Open circles show the median SFR in bins of halo mass, with the error bars indicating the 16–84th percentile scatter. Right-hand panels: distribution of galaxies selected by their total IR luminosity for luminosities of $10^{12.5}$–$10^{12.8}$ (green), $10^{11.5}$–$10^{11.8}$ (red), $10^{10.5}$–$10^{10.8}$ (blue) and $10^{9.5}$–$10^{9.8}$ $h^{-2} L_{\odot}$ (orange contours). The open symbols indicate the median halo mass and SFR in the corresponding luminosity bin, with the error bars indicating the 16–84th percentile scatter in halo mass.
leading to the downturn in the HOD. Galaxy mergers bring in a fresh reservoir of cold gas to central galaxies, allowing further star formation in these high mass ($\sim 10^{13} h^{-1} M_\odot$) haloes without the need for in situ gas cooling.

3.3.2 The evolution of SMG clustering

We show the evolution of the correlation length $r_0$ in the left-hand panel of Fig. 6. This is approximately constant for $z \lesssim 2$ but increases with increasing redshift at higher redshifts. The error bars shown are derived from the 1σ volume bootstrap errors described above.

In the right-hand panel of Fig. 6, we show the evolution of the large-scale bias with redshift, in addition plotting for reference the large-scale bias with redshift, in addition plotting for reference the evolution of the large-scale bias for haloes selected by their mass.

We can see that the bias evolution of our galaxies is of a similar form to that of the haloes, indicating that SMGs typically reside in haloes of $10^{11} - 10^{12} h^{-1} M_\odot$, over a large redshift range. This is in agreement with our previous findings in Fig. 5.

In Fig. 6, we compare to the observational results of Hickox et al. (2012) and Blain et al. (2004). Hickox et al. use sub-mm sources from the single-dish LESS source catalogue (Weiβ et al. 2009), with $S_{850 \mu m} \gtrsim 4.5$ mJy, at redshifts of $z \sim 2-4$, covering 0.35 deg$^2$, and use the cross-correlation of these with Spitzer/Infra-Red Array Camera selected galaxies over a similar redshift range, taking into account the photometric redshift probability distribution of their SMGs (Warlow et al. 2011), to derive a large-scale bias of $3.4 \pm 0.8$ from which they find a correlation length of $r_0 = 7.7^{+1.1}_{-1.4} h^{-1}$ Mpc assuming a power-law correlation function $\xi(r) = (r/r_0)^{-\gamma}$ with $\gamma = 1.8$. Blain et al. also assume a power-law $\xi(r)$ with $\gamma = 1.8$, and a Gaussian redshift distribution (Chapman et al. 2005), whilst allowing $r_0$ to vary in order to match the number of SMG ($S_{850 \mu m} \gtrsim 5$ mJy) pairs observed across a number of non-contiguous SCUBA fields with a combined area of $\sim 0.16$ deg$^2$.

They obtain a correlation length of $r_0 = 6.9 \pm 2.1 h^{-1}$ Mpc but note that if they exclude the most overdense field from their analysis, they derive $r_0 = 5.5 \pm 1.8 h^{-1}$ Mpc, which is in better agreement with our predictions. However, due to the significant errors on the observational data and potential biases due to the single-dish beam used in these studies which we discuss in Section 4, it is difficult to draw any strong conclusions about the level of agreement between the model and data.

From comparing the left-hand panel of Fig. 6 to that of Fig. 2, we can see that the clustering evolution of our SMG populations are remarkably similar to that of our most IR luminous galaxies ($L_{IR} = 10^{12} - 10^{12.5} h^{-2} L_\odot$). We note that at $z = 2.6$ the median 850 µm flux for galaxies in our most luminous $L_{IR}$ bin ($10^{12} - 10^{12.5} h^{-2} L_\odot$) is $3.3^{+2.2}_{-1.5}$ mJy, where the error bars represent the 10–90 percentiles. Conversely, at the same redshift the $S_{850 \mu m} > 4$ mJy population has a bolometric dust luminosity of $L_{IR} = 10^{12.04} - 10^{12.44} h^{-2} L_\odot$ (10–90 percentiles). Thus in our model the 850 µm selection selects the most IR luminous starburst galaxies (our predicted galaxy number counts at 850 µm are dominated by starburst galaxies for $S_{850 \mu m} > 0.2$ mJy), hence the similarities in the model predicted clustering evolution of SMGs and the most IR luminous galaxies.

3.3.3 SMG descendants and environment

Arguments which assume that the majority of $z = 0$ stellar mass of an SMG descendant is formed during the sub-mm bright phase imply that by fading the stellar population, SMGs could evolve on to the $z = 0$ scaling relations of massive ellipticals (assuming a burst duration of typically $\sim 100$ Myr; e.g. Swinbank et al. 2006; Simpson et al. 2014). Here we investigate the stellar and halo masses of the $z = 0$ descendants, presenting our findings for the bright population ($S_{850 \mu m} > 4$ mJy) in Fig. 7.

We find that across all redshifts shown in Fig. 7, which span the majority of the redshift distribution for this population, the selected galaxies evolve into galaxies with a stellar mass of $\sim 10^{11} h^{-1} M_\odot$ at the present day. This is similar to the results presented from an analysis of an earlier version of the galaxy formation model used here (González et al. 2011).
The clustering of dusty star-forming galaxies

Figure 5. Probability distribution of halo mass (left) and HOD (right) for 850 $\mu$m selected SMGs at $z = 3.1$ (top) and 2.1 (bottom). The blue, red and green lines indicate the HOD for the $S_{850\mu m} > 0.25, 1.0$ and 4.0 mJy, respectively, with the dashed (dotted) lines depicting satellite (central) galaxies. A horizontal dash–dotted line is drawn in both right-hand panels at $\langle N_{\text{SMGs}} \rangle = 1$ for reference.

Figure 6. Left-hand panel: evolution of the comoving correlation length $r_0$ [defined such that $\xi(r_0) = 1$] with redshift, for galaxies with $S_{850\mu m} > 0.25, 1.0$ and 4.0 mJy (blue, red and green lines, respectively). The errors indicate 1σ volume bootstrap errors for the $S_{850\mu m} > 4.0$ mJy population. The observational data are taken from Hickox et al. (2012; squares) and Blain et al. (2004; triangles). Right-hand panel: symbols and coloured lines as for the left-hand panel but indicating the evolution of the large-scale bias. The dotted, dashed and dash–dotted lines indicate the bias evolution for haloes of $M_{\text{halo}} > 10^{11}$, $10^{12}$ and $10^{13} h^{-1} M_\odot$, respectively, as measured directly from the MR7 simulation.
z = 0 descendants is broad, spanning nearly two orders of magnitude \( \sim 10^{12} - 10^{14} \, h^{-1} M_\odot \). In our model it appears that bright SMGs do not necessarily trace the most massive \( z = 0 \) environments. As with stellar mass, here we consider unique haloes, such that if a halo contains two galaxies selected at a given redshift, or the \( z = 0 \) descendant(s) of two galaxies selected at a given redshift, it is only counted once.

Our results for stellar and halo masses of bright SMGs and their descendants are a factor of \( \sim 5 \) lower than those found by Muñoz Arancibia et al. (2015). However, their simulations do not self-consistently predict the sub-mm flux of galaxies as is done in this work, but instead rely on a 'count-matching' approach to link a galaxy’s physical properties to its sub-mm flux. They infer median stellar and halo mass of \( 10^{11.2} \) and \( 10^{12.7} \, h^{-1} M_\odot \), respectively, for SMGs; and \( 10^{11.7} \) and \( 10^{13.8} \, h^{-1} M_\odot \), respectively, for the \( z = 0 \) descendants of SMGs.

4 ANGULAR CLUSTERING AT 850 \( \mu M \)

The simplest measure of clustering from a galaxy imaging survey is the angular two-point correlation function \( w(\theta) \). Analogously to equation (1), the probability of finding two objects separated by an angle \( \theta > 0^\circ \) is defined as

\[
\delta P_\delta(\theta) = \eta^2 [1 + w(\theta)] \delta \Omega_1 \delta \Omega_2, \tag{6}
\]

where \( \eta \) is the mean surface density of objects per unit solid angle and \( \delta \Omega_2 \) is a solid angle element, such that \( w(\theta) \) represents the excess probability of finding objects at angular separation \( \theta \), compared to a random (Poisson) distribution.

In this section we present the angular correlation function of galaxies, \( w_\ell \), selected by their 850 \( \mu m \) emission. We compare this to the angular correlation function of sub-mm sources, \( w_\ell \), extracted from simulated single-dish 850 \( \mu m \) imaging following the method presented in Cowley et al. (2015), and the angular correlation function of 850 \( \mu m \) intensity fluctuations, \( w_1 \).

4.1 The angular clustering of galaxies

Angular clustering, \( w(\theta) \), can be thought of as the on-sky projection of \( \xi(\ell, z) \), weighted by the number density of selected objects at a given redshift. We therefore use the approximation of Limber (1953) to calculate \( w_\ell \) from \( \xi(\ell, z) \), the spatial two-point correlation function. This assumes that the selection function (redshift distribution) of galaxies changes slowly over the comoving separations \( r \) for which \( \xi(\ell, z) \) is appreciably non-zero. Assuming a flat cosmology (as we do throughout), this allows \( w_\ell \), to be related to \( \xi(\ell, z) \) by

\[
w_\ell(\theta) = \frac{\int N(z) \frac{d^2 \xi}{d\ell d\mu} d\mu d\ell}{\int [N(z)]^2 d\mu d\ell}, \tag{7}
\]

where \( N(z) \) is the predicted redshift distribution of the selected galaxies, \( \frac{d^2 \xi}{d\ell d\mu} = H_0 E(z) / c \) with \( E(z) = [\Omega_m(1 + z)^3 + \Omega_\Lambda]^{1/2} \), corresponds to the comoving radial distance to redshift \( z \). The comoving line-of-sight separation \( u \) is defined by \( r = [u^2 + \chi^2 \sigma^2]^{1/2} \), where \( \sigma^2 / 2 = [1 - \cos(\theta)] \). We present \( w_\ell \) for our sub-mm-selected galaxy populations, as defined in the previous section, in Fig. 8.

\[ \text{Figure 7. The descendants of} \ S_{850, \mu m} > 4.0 \, mJy \text{selected galaxies in our simulation. The squares and triangles indicate the median stellar and host halo mass of the selected galaxies, respectively, with the filled symbols indicating this quantity at the redshift of interest and the open symbols indicating this quantity for the} \ z = 0 \text{ descendant. The error bars indicate 10–90 percentile ranges. The open squares and filled triangles are offset in redshift by } \pm 0.025 \text{ for clarity. A dotted horizontal line is drawn at } M = 10^{11} \, h^{-1} M_\odot \text{ for reference.}
\]
4.2 The angular clustering of single-dish sources

To make predictions for the angular clustering from sub-mm sources that would be observed in single-dish surveys, we simulate such observations using the method presented in Cowley et al. (2015).

Briefly, we generate lightcone catalogues of simulated SMGs using the method described in Merson et al. (2013). We include in our lightcone catalogue galaxies brighter than the flux at which 90 per cent of the predicted CIB at 850 μm is recovered. The predicted value of the CIB is in good agreement with the observations of Fixsen et al. (1998), and thus gives our image a realistic background. The galaxies are then binned into pixels according to their on-sky position, with the flux value of a pixel being the sum of the fluxes of all the galaxies within it. The pixel scale is chosen such that the beam is well sampled. This image is then smoothed with a Gaussian with an FWHM chosen to be equal to that of the beam used in observational studies following which Gaussian white noise is added of a magnitude comparable to that found in observations. The image is constrained to have a mean of zero by the subtraction of a uniform background, and then matched-filtered prior to source extraction. Sources are found by iteratively identifying the maximal pixel in the map and subtracting off the matched-filtered PSF scaled to and centred on the value and position of the pixel. For simplicity, the position of the source is recorded as being at the centre of the pixel in the map and subtracting off the matched-filtered PSF scaled to zero over the area of the field, where \( \sigma_{\text{conf}} \) is the true mean surface density. This causes the mean angular correlation function to be underestimated by an average amount

\[
\sigma^2 = \frac{1}{\Omega^2} \int \int w_{\text{true}}(\theta) \, d\Omega_1 \, d\Omega_2, \tag{8}
\]

(Groth & Peebles 1977) due to the integral constraint (that by construction the estimated angular correlation function will integrate to zero over the area of the field), where \( w_{\text{true}}(\theta) \) is the true angular correlation function of the sources and the angular integrations are over a field of area \( \Omega \). This quantity is related to the field-to-field variation in the number counts through

\[
\sigma^2 = \frac{(\langle n \rangle - \langle \eta \rangle)^2}{\langle \eta \rangle^2} - \frac{1}{\langle \eta \rangle}, \tag{9}
\]

(e.g. Efstathiou et al. 1991). We evaluate equation (9) for our 50 × 4 deg² lightcones and find \( \sigma^2 = 4.8 \times 10^{-3} \), which we add on to our computed angular correlation functions for sub-mm sources (\( w_\gamma \)).

In Fig. 8 we show the mean \( w_\gamma(\theta) \) from the 50 lightcone realizations (magenta line), with the corresponding shaded region indicating the 1σ (16–84th percentile) field-to-field variation in \( w_\gamma(\theta) \) in each bin of angular separation. In Fig. 9 we compare \( w_\gamma(\theta) \) with observational estimates from the 0.35 deg² LESS source catalogue...
(Weiß et al. 2009, 19 arcsec FWHM, $S_{850\mu m} > 4.5$ mJy); and from sources identified from a compilation of non-contiguous SCUBA fields totalling $\sim 0.13$ deg$^2$ in area (Scott, Dunlop & Sriejant 2006, 15 arcsec FWHM, $S_{850\mu m} > 5$ mJy). The magenta, cyan and orange shaded regions indicate the $2\sigma$ (2.25–97.75th percentile) field-to-field variation in each bin of angular separation we predict for fields of 4, 1 and 0.5 deg$^2$, respectively, which must be considered when comparing theory and observations. For this we recalculate the angular correlation function for each field considering only sources within the central 1 or 0.5 deg$^2$. As in Fig. 6, the large error bars of the observational data make a detailed comparison difficult and highlight the need for larger sub-mm surveys. We note however, that our predictions are consistent with the data once field-to-field variations are taken into account.

### 4.3 Blending bias in the angular clustering of single-dish sources

One of the key results of this work, evident in Fig. 8, is that the angular correlation function of sources, $w_\gamma$, is greater in amplitude by a factor of $\sim 4$ than the angular correlation function of galaxies, $w_g$, for the source flux limit used here (4 mJy). In this section, we investigate the dependence of this effect on a number of factors, and conclude that it is due to confusion in the simulated survey caused by the 15 arcsec FWHM beam. This blends the emission of multiple, typically physically unassociated galaxies (Cowley et al. 2015), with an on-sky separation comparable to or less than the size of the beam, into an object recognized as a single source by the source extraction algorithm. Thus the angular distribution of sources found in the simulated map is different from the angular distribution of the input galaxies. We label this effect ‘blending bias,’ $b_w$, where $b_w = [w_g(\theta)/w_\gamma(\theta)]$, and note that a similar effect has been observed in low-resolution X-ray surveys (e.g. Vikhlinin & Forman 1995; Basilakos et al. 2005).

In the upper panel of Fig. 10, we test how sensitive this bias is to the size of the beam and ‘instrumental’ noise. We repeat the calculation for deriving the angular correlation function of single-dish sources for images generated using Gaussian beams with FWHM of 30 and 7.5 arcsec. We kept the instrumental noise constant at $\sigma_\text{inst} = 1$ mJy beam$^{-1}$ in each case and used the same flux limit of $S_{850\mu m} > 4$ mJy to select our sources, noting that varying the beam size will change the confusion in the image and thus the overall noise. We derived blending bias factors in $w_\gamma$ of $b_w^2 \sim 2$ and $b_w^2 \sim 8$ for the 7.5 and 30 arcsec beams, respectively. We tested the effect of instrumental noise by creating a set of images with a 15 arcsec beam, but without the addition of instrumental noise. This can be seen in Fig. 10 to have a negligible effect on the angular correlation function of the sources, as one would expect given that our ‘instrumental’ noise is random and has no dependence on scale.

In the lower panel of Fig. 10, we repeat the calculation on images which had the positions of galaxies with $S_{850\mu m} < 2$ mJy and $z > 2.5$ randomized prior to being created and find that the blending bias is reduced to $b_w^2 \sim 2$. For maps which had the position of all galaxies with $S_{850\mu m} < 2$ mJy randomized the blending bias is approximately unity, i.e. has been removed. Although not shown...

---

8 In Cowley et al. (2015), we showed that this confusion effect boosts the cumulative 850 $\mu m$ number counts by a factor of $\sim 2$ at $S_{850\mu m} = 4$ mJy for a 15 arcsec FWHM beam. See also Hayward et al. (2013) and Muñoz Arancibia et al. (2015), who investigate the effect of coarse angular resolution on the observed sub-mm number counts.
and dark matter, we calculate the angular correlation function over a given redshift interval by appropriately changing the limits in the Limber (1953) equation (7). An example of this is shown in the upper panel of Fig. 11 for two redshift intervals centred on $z = 2.5$, $2.25 < z < 2.75$ (solid lines) and $1.0 < z < 4.0$ (dashed lines). In this way we can derive a large-scale bias, defined as $|w(\theta)/w_{\text{DM}}(\theta)|^{1/2}$, for the galaxies and source-counterparts, as a function of redshift interval considered. This is shown in the bottom panel of Fig. 11, where we consider 8 redshift intervals of varying width centred on $z = 2.5$. We can see that the derived source-counterpart bias, which is affected by blending bias, increases monotonically as the width of the redshift interval increases whilst the bias derived from the angular correlation function of galaxies is approximately constant and consistent with the bias derived from the spatial correlation function (see Section 3.3) for all redshift intervals considered. Also evident in this panel is how the halo mass can be significantly overestimated as a result of this effect. As a further example of this, using equation (8) in Sheth, Mo & Tormen (2001) to infer halo mass from a measured bias, we find that doubling the bias (i.e. $b_h = 2$) of haloes with mass $10^{12} \ h^{-1} \ M_\odot$ yields an inferred halo mass of $10^{13.1} \ h^{-1} \ M_\odot$ at a redshift of 2.5, an overestimation of more than an order of magnitude.

To further illustrate the results in this section, we imagine a simplified scenario with two distinct redshift intervals A and B and two angular positions $\theta_A$ and $\theta_B$. Within each redshift interval the positions of galaxies will be correlated according to some $w(S_A, S_B, z, \Delta z, \theta_A - \theta_B)$, and we define some flux limit $S_{\text{lim}}$ brighter than which galaxies will be resolved as point sources in the beam-smoothed imaging and fainter than which they would require some boost to be counted in the single-dish catalogue.

If we now consider the effect of the beam, we have a beam-smoothed flux density field in each redshift interval, $S(\Omega_{\text{beam}}, z, \Delta z, \theta)$, dominated by galaxies with $S < S_{\text{lim}}$, the distribution of which will be correlated with the positions of galaxies with $S > S_{\text{lim}}$ in that interval, according to $w$. It is also now possible for flux from B to boost objects (at the same on-sky position) in A into the selection (and vice versa). This induces an artificial cross-correlation between the sources selected in A and B, as some objects in B required a flux boost from A to be considered and this flux is correlated with selected objects in A. Thus we make the prediction that the cross-correlation of single-dish source counterparts (for sources with $S_{\text{lim}} > 4 \text{ mJy}$) in distinct redshift intervals will be non-zero, even in the absence of effects such as gravitational lensing which are not considered here.

This is demonstrated in Fig. 12, where we show the angular cross-correlation between source counterparts in two distinct redshift intervals $1.0 \leq z < 2.4$, $z_A$, and $2.6 \leq z < 4.0$, $z_B$. This is found to be non-zero whilst the equivalent calculation for bright galaxies (with $S_{\text{lim}} > 2 \text{ mJy}$) is zero (cyan line). We also find that source counterparts in $z_A$ are correlated with bright galaxies in $z_B$, in this case shown for galaxies with $S_{\text{lim}} > 2 \text{ mJy}$ (green line). The physical correlation of the faint with the bright galaxies in $z_B$ has caused the sources from $z_A$, many of which were selected as sources because of a flux contribution from faint galaxies in $z_B$, to be correlated with bright galaxies in $z_B$. This is an induced correlation introduced by the finite beam. When we repeat the source–galaxy cross-correlation using sources from maps which had the positions of galaxies with $S_{\text{lim}} < 2 \text{ mJy}$ and $z > 2.5$ randomized prior to the image being created, the randomization removes the physical correlation between faint and bright galaxies in $z_B$, thus we find that the induced cross-correlation between sources in $z_A$ and bright galaxies in $z_B$, on scales larger than the beam, is now zero. This is despite the fact the positions of galaxies with $S_{\text{lim}} > 2 \text{ mJy}$ in $z_B$ were not changed.

We infer that it is these induced cross-correlations that cause the trend in blending bias with redshift interval width seen in the lower panel of Fig. 11, as increasing the redshift interval increases the number of induced cross-correlations considered. It also explains the trends seen in the lower panel of Fig. 10, as randomizing the positions of faint galaxies reduces the correlation between the distribution of flux density, $S$, and the distribution of galaxies with $S > S_{\text{lim}}$ at a given redshift, and thus the contribution of the induced cross-correlation terms. For the same $S_{\text{lim}}$ increasing the beam size will on average increase the multiplicity of sources. As the component of each source are, in our simulations, drawn from different

---

9 Here we use a limit of 2, rather than 4 mJy, so we have enough objects for a robust determination of $w_{\text{cross}}$. We do not expect the result to be sensitive to this given that the autocorrelation of galaxies is roughly independent of flux over this flux range.
The function \( w_1(\theta) \) can be expressed as a flux-weighted integral of the angular correlation function of galaxies, \( w_1 \), such that

\[
w_1(\theta) = \frac{1}{(I)^2} \left[ \int \int w_1(S_1, S_2, \theta) S_1 S_2 \frac{dn_1}{dS_1} \frac{dn_2}{dS_2} dS_1 dS_2 + \delta^2(\theta) \int S^2 \frac{dn}{dS} dS \right].
\]

where \( w_1(S_1, S_2, \theta) \) is the angular cross-correlation of galaxies with fluxes \( S_1 \) and \( S_2 \) and \( d\eta/dS \) is the surface density per unit solid angle of galaxies with flux \( S \). The angular cross-correlation of galaxies

\(^{10}\) In this section, for ease of reading, and as here we are only considering a single band (850 \( \mu \)m), we suppress the explicit frequency dependence in our notation. For example, we write the mean intensity at a given observed frequency \( \nu \), \( \langle I \rangle \), as \( \langle I \rangle \).
\[ w_\theta(S_1, S_2, \theta) \text{ derives from a more general form of equation (7) such that} \]
\[ w_\theta(S_1, S_2, \theta) = \int \frac{N_i(z)N_j(z)}{\int N_i(z)dz} \frac{d\theta}{\int N_j(z)dz}, \]
where \( N_i(z) \) represents the redshift distribution of galaxies with flux \( S_i \) and \( \xi(S_1, S_2, r, z) \) is the spatial cross-correlation of galaxies with \( S_1 \) and \( S_2 \) at redshift \( z \). We can recover \( w_\theta \) for an individual galaxy population by integrating \( w_\theta(S_1, S_2, \theta) \) over the flux limits defining the selection of the population. The term containing the Dirac delta function \( \delta(\theta) \) on the right-hand side of equation (12) is the shot noise, which arises from galaxies being approximated as point sources.

We can calculate \( w_\theta \) for the clustered galaxy population directly from our simulated images using the estimator
\[ w_\theta(\theta) = \sum_{ij} \delta_i \delta_j \Theta_{ij}, \]
where \( \delta_i \) is the fractional variation of flux in the \( i \)th pixel and is calculated using \( \delta_i = (S_i / \langle S \rangle) - 1 \) where \( S_i \) is the flux value of the \( i \)th pixel and \( \langle S \rangle \) is the average flux value of a pixel, as all of our pixels are of equal area. The step function \( \Theta_{ij} \) is 1 if pixels \( i \) and \( j \) are separated by a distance in the angular bin \( \theta \pm \Delta \theta / 2 \) and zero otherwise. However, in practice it is more computationally efficient to make use of the fact that \( w_\theta \) can be obtained from the angular power spectrum of CIB anisotropies, \( P_\nu(k_0) \), using a Fourier transform such that
\[ w_\theta(\theta) = \frac{2\pi}{(1)^2} \int P_{\nu}(k_0)J_0(2\pi r_0 \theta)k_0dk_0, \]
where \( J_0 \) is the zeroth-order Bessel function of the first kind and the convention \( k_0 = 1/\lambda_0 \) is used. We therefore compute \( P_{\nu}(k_0) \) directly from our simulated images, prior to any matched-filtering, and make use of equation (15) to calculate \( w_\theta \). This quantity is shown in Fig. 13 (gold line), with the corresponding shaded region indicating the 1σ percentile variation of our 50 lightcone realizations at a given \( \theta \). The Gaussian-like profile on small scales (\( \theta < 30 \) arcsec) is due to the beam used to convolve the simulated image and is mostly produced by the shot noise term in equation (12). It can be seen that on scales larger than the beam \( w_\theta \) is very similar to \( w_{\nu} \), which is unsurprising given that \( \sim 70 \) per cent of the total background light predicted by the model at 850 \( \mu \)m is produced by galaxies with \( S_{850\mu m} > 0.25 \) mJy.

5 ANGULAR POWER SPECTRUM OF CIB ANISOTROPIES

The galaxies which contribute to the bulk of the CIB cannot be individually resolved with current instruments, and instead information regarding their clustering and hence the masses of the haloes they occupy is derived from observations of the clustering of fluctuations in the background light. Therefore, in this section we compare predictions with recent measurements of the angular power spectrum of CIB anisotropies \( P_{\nu}(k_0) \). Here \( \nu \) is a fixed observed frequency [related to the emitted frequency, \( v_e \), by \( \nu = v_e(1 + z)^{-1} \)].

The angular power spectrum of CIB anisotropies was introduced in equation (15) and can be expressed as an integral over redshift of the 3D power spectrum of fractional emissivity fluctuations \( P'_{\nu}(k, z) \), where spatial wavenumber \( k \) is related to spatial wavelength \( \lambda \) by the convention \( k = 2\pi / \lambda \). Using the approximation of Limber (1953), the small-angle approximation \( (k_0 \gg 1) \) and assuming a flat cosmology, we can write \( P'_{\nu}(k_0) \) (for \( k_0 \) in units of \( \text{radian}^{-1} \)) as
\[ P'_{\nu}(k_0) = \int \frac{d\theta}{\int N_i(z)dz} \left( \frac{a}{\chi} \right)^2 P'_{\nu}(k = 2\pi k_0 / \chi, z) \]
(e.g. Viero et al. 2009; Shang et al. 2012). Here \( \chi \) is the radial comoving distance to redshift \( z, a = (1 + z)^{-1} \) is the cosmological scale factor and \( (j_\nu(z)) \) describes the mean emissivity per unit solid angle at redshift \( z \), which can be expressed as
\[ (j_\nu(z)) = \int dL_\nu \frac{dn}{dL_\nu} (L_\nu, z) \left( \frac{L_\nu}{4\pi} \right), \]
and related to the mean intensity (see equation 11) by
\[ \langle I_\nu \rangle = \int dz \frac{d\chi}{dz} a(j_\nu(z)). \]

In our model, not all haloes contribute equally to \( (j_\nu(z)) \). We can therefore define a differential emissivity \( d\nu / d\log_{10} M_b \) (e.g. Shang et al. 2012; Béthermin et al. 2013) such that equation (16) can be expressed as
\[ P'_{\nu}(k_0) = \int \int d\log_{10} M_b d\log_{10} M'_b \frac{d\chi}{dz} \left( \frac{a}{\chi} \right)^2 \times \frac{d\nu}{d\log_{10} M_b} \frac{d\nu}{d\log_{10} M'_b} P'_{\nu}(k, M_b, M'_b, z), \]
where \( P'_{\nu}(k, M_b, M'_b, z) \) is the 3D cross-spectrum of fractional emissivity fluctuations, between haloes of mass \( M_b \) and \( M'_b \).

Whilst in principle it is possible to calculate \( (j_\nu(z)) \) and \( P'_{\nu}(k, z) \) from the output of our model, for simplicity we compute \( P'_{\nu}(k_0) \)
from a simulated image of a lightcone catalogue at the wavelength of interest.

Here, as we compare $P_\nu(k_0)$ predicted by the model to recent Herschel-SPIRE data (Viero et al. 2013), we use wavelengths of 250, 350 and 500 μm, and a Gaussian beam with an FWHM of 18, 25 and 36 arcsec, respectively, to create our imaging. For simplicity we do not add any instrumental noise to these maps. Following the procedure outlined earlier we generate a lightcone catalogue including galaxies brighter than the flux at which we recover 90 per cent of the predicted CIB at the wavelength of interest (this predicted CIB agrees well with the observations of Fixsen et al. 1998 at all wavelengths) and choose a pixel scale such that the beam is well sampled. We generate $3 \times 20$ deg$^2$ lightcones in order to have a similar total area to that used by Viero et al.

First, we show the differential emissivity of our model (described above) at 350 μm in Fig. 14, in terms of the contribution from central and satellite galaxies. The contribution from central galaxies peaks in the halo mass range $10^{11.5} - 10^{12} h^{-1} M_\odot$ at all redshifts, with the peak evolving modestly from lower to higher halo masses from $z = 5$ to $z = 2$, and then being approximately constant for $z < 2$. The contribution from satellite galaxies spans a broader range of halo mass and peaks at higher halo mass; however, it is much smaller than that of the central galaxies, being only $\sim 6$ per cent of the total 350 μm emissivity at $z = 3.1$ and only $\sim 14$ per cent at $z = 0.5$.

In Fig. 15 we compare $P_\nu(k_0)$ predicted by our model to the observations of Viero et al. (2013). The horizontal dashed line in each panel represents the predicted shot noise. This is the power that would be expected if the background were composed of an un-clustered population of point sources and as such has no scale dependence. It is related to the number counts of the model by

$$P_{\text{shot}}^\nu = \int_0^{S_{\text{cut}}} S_\nu^2 \frac{dn}{dS_\nu} dS_\nu,$$

(e.g. Tegmark & Efstathiou 1996), where $S_{\text{cut}}$ is the limit above which sources can be resolved and are therefore removed/masked from further analysis in order to reduce the shot noise.$^{12}$ Note that this contribution to the power spectrum corresponds to the Dirac delta function term in equation (12).

We show the two extremes of masking schemes applied by Viero et al. to their data, in order to reduce the shot noise in their images. They identified sources by finding peaks $> \sigma$ in the matched-filtered SPIRE images at each wavelength. Sources above a given flux limit ($S_{\text{cut}}$) were then masked by circles with a 1.1 × FWHM diameter, before calculating the power spectra. Extended sources were removed by using the criterion $S_{\text{cut}} = 400$ mJy. We compare to the most extreme masking case $S_{\text{cut}} = 50$ mJy (open squares) and mimic the masking applied by Viero et al. (2013) by excluding galaxies with $S_\nu > 50$ mJy prior to the creation of our simulated images. We have tested that masking pixels in the full image produces near identical results.

At 350 and 500 μm we also compare our predictions to the observational data of the Planck Collaboration (XXX, 2014). These authors employ a slightly different masking scheme to that used by Viero et al.; however, this has a negligible effect on the scales covered by their data. Encouragingly, both observational data sets are in good agreement.

We note that there is a discrepancy between the model predictions and the observational data of a factor $\sim 2$ over all wavelengths and angular scales. Whilst this represents much better agreement than for previous versions of our model (e.g. Kim et al. 2012), we investigate whether it is possible to further improve this by forcing a better agreement between our predicted number counts and those that are observed. By construction, this gives us the observed surface density of objects and should make the shot noise terms equal. This is merely an illustrative exercise to replicate one of the freedoms of empirical models which are constrained to match the observed counts e.g. HOD modelling. An example of this is shown in Fig. 16.

12 Imposing the limit $S_{\text{cut}}$ is necessary as for Euclidean number counts ($dn/dS \propto S^{-2.5}$) the integral in equation (20) does not converge.
where we scale the fluxes of our galaxies by the function shown in the bottom panel, chosen such that it brings our model number counts into better agreement with the observed data (top panel). We then apply this scaling relation to our galaxies prior to the creation of our simulated images and recalculate the power spectrum, resulting in the dashed red line in Fig. 15. This exercise produces power spectra in much better agreement with the observed data, even at low values of \( k_0 \) where clustering dominates over the shot noise. We recognize that this is an artificial adjustment to our model. However, it is a relatively minor one as we do not adjust the flux of our galaxies by more than \( \sim 40 \) per cent across all three bands. We do not draw strong conclusions from this, but simply note that good agreement with the observed number counts is required to reproduce the observed power spectra. In this case we have adjusted our number counts artificially but in future this could be achieved by developments to the treatment of physical processes in the model.

At 250 \( \mu m \) there remains a small \( (\sim 25 \text{ per cent}) \) discrepancy between the observed shot noise and that predicted by our flux rescaling, despite the fact that the number counts are in close agreement \( (\sim 14 \text{ per cent}) \). We attribute this to field-to-field variation between the fields used to measure the observed number counts and those used for measuring power spectra, and the uncertainties on both measurements.

As the FIR emissivity is dominated by a halo mass range of \( 10^{11.5} - 10^{12} h^{-1} M_{\odot} \) (e.g. at 350 \( \mu m \) and \( z = 3.1 \), 54 per cent of the total emissivity comes from haloes in this mass range) we investigate whether this mass range also contributes most to the angular power spectrum of CIB anisotropies. We retain the masking flux limit of \( S_{\text{cut}} = 50 \text{ mJy} \) from Viero et al. and divide our lightcone catalogue into three halo mass bins of 0.5 dex width, which span the peak of the differential emissivity distribution shown in Fig. 14. We then construct an image for each bin. The cross-power spectra for these images are shown in Fig. 17. We have ignored the contribution from haloes outside the mass bins chosen for this plot; however, the bins chosen contribute \( \sim 90 \) per cent of the total power spectrum (for \( S_{350 \mu m} < 50 \text{ mJy} \)). We can see that the same halo mass bin which dominates the emissivity dominates the contribution to the power spectrum, as one might expect if the fractional cross-power spectrum term, \( P^e(k, M_h, M_{\text{cut}}, z) \), in equation (19) is a smoothly varying function of halo mass, given the peaked nature of the \( dP/d\log_{10}M_h \) term.

To investigate the fluxes of the galaxies which contribute most to the power spectrum, we divide our lightcone catalogue into four flux bins and construct an image for each. The cross-power spectra for these images shown for 350 \( \mu m \) in Fig. 18. We can see immediately that on larger angular scales \( (k_0 \lesssim 0.1 \text{ arcmin}^{-1}) \) the power is dominated by galaxies in the faintest bin \( S_\nu < 5 \text{ mJy} \) (e.g. top-left panel), whilst the shot noise is dominated by brighter galaxies (e.g. bottom-right panel). In our model the dominant shot noise contribution at 350 \( \mu m \) (for galaxies with \( S_{350 \mu m} < 50 \text{ mJy} \)) comes from galaxies with \( S_{350 \mu m} \sim 20 \text{ mJy} \).

6 SUMMARY

We present predictions for the clustering evolution of dusty star-forming galaxies selected by their total IR luminosity \( (L_{\text{IR}}) \), and their emission at FIR and sub-mm wavelengths. This includes the first predictions for potential biases on measurements of the angular clustering of these galaxies due to the coarse angular resolution of the single-dish telescopes used for imaging surveys at these wavelengths. Our model incorporates a state-of-the-art semi-analytic model of hierarchical galaxy formation, a dark matter only \( N \)-body simulation which utilizes the WMAP7 cosmology and a simple model for calculating the emission from interstellar dust heated by stellar radiation, in which dust temperature is calculated self-consistently.

We present predictions for the spatial clustering of galaxies selected by the total IR luminosity \( L_{\text{IR}} \sim 10^9 - 10^{12} h^{-2} L_{\odot} \) for \( z = 0 - 5 \). We find that the clustering evolution in our model depends on the luminosity of the selected galaxies. The large-scale bias evolution of our most luminous galaxies \( (10^{12} - 10^{12.5} h^{-2} L_{\odot}) \) is consistent with them residing in haloes of mass \( 10^{14} - 10^{12} h^{-1} M_{\odot} \) over this redshift range. In the model, this halo mass range is the one most conducive to star formation over these redshifts. For lower luminosity populations the range of halo masses selected changes with redshift, such that generally they move to higher mass haloes with increasing redshift.

We find that 850 \( \mu m \) selected galaxies in our model represent a clustered population, with an \( S_{850 \mu m} > 4 \text{ mJy} \) selected sample having a correlation length of \( r_0 = 5.5^{+0.3}_{-0.5} h^{-1} \text{ Mpc} \) at \( z = 2.6 \), consistent with observations of Hickox et al. (2012) and Blain et al. (2004). The bias with which they trace the dark matter evolves with redshift in a way consistent with the SMGs.
residing in haloes of $10^{11.5} - 10^{12} \, h^{-1} \, M_\odot$ up to a redshift of $z \sim 4$. This result is insensitive to the flux limit used to select the galaxies for $0.25 \lesssim S_{850 \mu m} \lesssim 4 \, mJy$, and we note that even at the faintest fluxes investigated ($S_{850 \mu m} \gtrsim 0.25 \, mJy$) the model predicted $850 \mu m$ number counts are dominated by starburst galaxies. Interestingly, the HOD for $850 \mu m$ central galaxies peaks well below unity. Halo abundance matching models which force the HOD of central galaxies to equal unity would place galaxies in much more massive haloes than our model, given the same galaxy number density. We find further that our brightest SMGs ($S_{850 \mu m} > 4 \, mJy$) evolve into $z=0$ galaxies with stellar mass $\sim 10^{11} \, h^{-1} \, M_\odot$, occupying a broad range of present-day halo masses $10^{12} - 10^{13} \, h^{-1} \, M_\odot$. Thus, in our model, bright SMGs do not necessarily trace the progenitors of the most massive $z=0$ environments. Our $850 \mu m$ selected galaxy populations share significant overlap with the IR luminous galaxy populations $L_{IR} \sim 10^{12} \, h^{-2} \, L_\odot$, and thus exhibit similar clustering evolution.

We make predictions for the angular clustering of sub-mm sources identified in the S2CLS. We show that the angular clustering of $850 \mu m$ single-dish selected sources is biased with respect to that of the underlying galaxy population, in our model by a factor of $\sim 4$. We attribute this ‘blending bias’ to the coarse angular resolution of single-dish telescopes blending the sub-mm emission of many (typically physically unassociated) galaxies into a single source. This induces cross-correlation terms between sources selected at different redshifts. The position of a galaxy at $z_A$ boosted into the source selection by fainter galaxies at some other redshift $z_B$ will thus be correlated with the positions of galaxies at $z_B$, some of which will already be included in the source selection. It is the addition of these induced cross-correlations that leads to the ‘blending bias’. The value of this bias depends on the size of the beam, the intrinsic clustering of the underlying galaxy population, and their number counts.

We caution that this severely complicates the interpretation of measurements of the angular clustering of SMGs derived from single-dish survey source catalogues, and if not considered could lead to the halo masses for SMGs being significantly overestimated. The angular clustering of galaxies selected at $850 \mu m$ in our model is insensitive to the flux limit used (as is the case for the spatial clustering), and agrees with the angular clustering of intensity fluctuations predicted by the model at that wavelength.

The FIR emissivity of our model is dominated by the emission from haloes in the mass range $10^{11.5} - 10^{12} \, h^{-1} \, M_\odot$ independent of redshift, and this halo mass range also dominates the angular power spectrum of CIB anisotropies. Our model agrees with the observed angular power spectrum of CIB anisotropies at $Herschel$-SPIRE wavelengths (250, 350 and 500 $\mu m$; Viero et al. 2013) to within a factor of $\sim 2$ over all scales, representing an improvement over previous versions of the model. This agreement can be further improved on by making minor ($\lesssim 40$ per cent) artificial adjustments to the fluxes of our galaxies which bring the predicted number counts into better agreement with those observed.

Galaxies selected by their FIR/sub-mm emission represent a large proportion of the cosmic star formation over the history of the...
The clustering of dusty star-forming galaxies

Figure 18. Power spectrum of the CIB predicted by our model at 350 μm divided into the following flux bins $0 \leq S_{350\mu m} < 5$ mJy, $5 \leq S_{350\mu m} < 10$ mJy, $10 \leq S_{350\mu m} < 20$ mJy and $20 \leq S_{350\mu m} < 50$ mJy. The diagonal panels indicate the autopower spectrum of the flux bin indicated in the panel and as such contains the shot noise term, indicated by the horizontal dashed line. The off-diagonal panels indicate the cross-power spectrum between different bins, as indicated in the panel. The solid grey line in each panel indicates the total power for $S_{\nu} < 50$ mJy, with the dashed grey horizontal line indicating the total shot noise.

Universe. As such, understanding the nature of these galaxies is critical to a full understanding of galaxy formation. In our model, the galaxies that contribute to the bulk of the CIB are predominantly disc instability triggered starbursts which reside in a relatively narrow range of halo masses $10^{11.5} - 10^{12} h^{-1} M_\odot$ for $z \lesssim 5$.

Abundance matching arguments which combine the observed stellar mass function with the theoretically predicted halo mass function at $z = 0$ imply that this is also the mass range for present-day haloes for which the conversion of baryons into stars has been most efficient (e.g. Guo et al. 2010). The stellar fraction in a halo depends on an integral over the past history of star formation in all of the progenitors of that halo. In our model, the fact that the conversion efficiency of baryons into stars peaks in present-day haloes of mass $\sim 10^{11.5} - 10^{12} h^{-1} M_\odot$ is a simple consequence of most of the star formation occurring in such haloes over a large range of redshifts ($z \lesssim 5$), combined with the growth of haloes by hierarchical structure formation. This in turn is a consequence of the physical prescriptions on which our model for galaxy formation is based, in particular for gas cooling in haloes and feedback from supernovae and AGN. Observationally, information regarding the host halo masses of selected galaxies can be derived from measurements of their clustering; however, extracting significant results from observations at FIR/sub-mm wavelengths is a challenging exercise. This work presents predictions which we hope will inform the interpretation of future observations.

ACKNOWLEDGEMENTS

The authors wish to thank Lingyu Wang and Chian-chou Chen for helpful discussions, and the anonymous referee for providing a detailed and constructive report.
