ABSTRACT Intermediate filaments are major cytoskeletal components whose assembly into complex networks and isotype-specific functions are still largely unknown. Caenorhabditis elegans provides an excellent model system to study intermediate filament organization and function in vivo. Its intestinal intermediate filaments localize exclusively to the endotube, a circumferential sheet just below the actin-based terminal web. A genetic screen for defects in the organization of intermediate filaments identified a mutation in the catalytic domain of the MAP kinase 7 orthologue sma-5(kc1). In sma-5(kc1) mutants, pockets of lumen penetrate the cytoplasm of the intestinal cells. These membrane hernias increase over time without affecting epithelial integrity and polarity. A more pronounced phenotype was observed in the deletion allele sma-5(n678) and in intestine-specific sma-5(RNAi). Besides reduced body length, an increased time of development, reduced brood size, and reduced life span were observed in the mutants, indicating compromised food uptake. Ultrastructural analyses revealed that the luminal pockets include the subapical cytoskeleton and coincide with local thinning and gaps in the endotube that are often enlarged in other regions. Increased intermediate filament phosphorylation was detected by two-dimensional immunoblotting, suggesting that loss of SMA-5 function leads to reduced intestinal tube stability due to altered intermediate filament network phosphorylation.

INTRODUCTION

Intermediate filaments, actin filaments, and microtubules are the main components of the metazoan cytoskeleton and are involved in most cellular processes. The contribution and properties of the three components differ, however. The least investigated elements are the molecularly highly diverse intermediate filaments. In contrast to actin filaments and microtubules, they are not essential for either cell division or basic cell functions. Yet mutations in intermediate filament genes have been implicated in more than 80 human diseases (Omary, 2009).

Intermediate filaments have unique mechanical properties. They are highly flexible and extensible but support, at the same time, cellular stiffness (Stamenovic and Wang, 2000; Ramms et al., 2013; Seltmann et al., 2013; Mendez et al., 2014). Their contribution to mechanical stress resilience is reflected by the large number of blister-forming diseases that are caused by single-point mutations of epithelial keratin intermediate filament–encoding genes (Homberg et al., 2015). Besides these mechanical functions, intermediate filaments are involved in the regulation of cell growth, apoptosis, and vesicle trafficking to name but a few other functions (Kim and Coulombe, 2007; Magin et al., 2007; Toivola et al., 2010). To facilitate these functions, intermediate filaments form complex three-dimensional networks whose arrangement depends on the cell type, cell cycle stage, and functional state.

A particularly striking arrangement of the intermediate filament cytoskeleton is encountered in intestinal epithelial cells. The bulk of intermediate filaments is concentrated in a dense fibrous layer just below the apical terminal web of actin and spectrin in these cells. These layers are anchored to the apical junctional complex in vertebrates including fish (Markl and Franke, 1988), amphibians (Maurizzi et al., 2000), and mammals (Iwatsuki and Suda, 2010). This remarkable distribution is also conserved in the nematode Caenorhabditis elegans, in which intermediate filaments localize to the prominent endotube (Bossinger et al., 2004; Carberry et al., 2009; Coch and Leube, 2016). It has been also observed in the basal hexapod Isotomurus maculatus, which—in contrast to other hexapods—expresses cytoplasmic intermediate filaments (Mencarelli et al., 2011). Taken together, these findings indicate it is likely that the highly conserved distribution pattern is advantageous to intestinal cells and suggests that it strengthens the mucosal barrier function (Geisler and Leube, 2016).

The intermediate filament–rich subapical network might form an intracellular barrier to the cytoplasmic space beneath and is closely attached to the organelle-free terminal web above, which serves as an anchor for the actin bundles that protrude into the microvilli of the overlying brush border (Hirokawa et al., 1982). The terminal web contains myosins, spectrins, actin, and an assortment of actin-binding proteins (see reviews in Mooseker, 1985; Fath and Burgess, 1995; Ku et al., 1999; Thomas, 2001). Assembly of the terminal web has been studied during gut development in vertebrates (Chambers and Grey, 1979), but its relationship to the intermediate filament network is still largely unexplored.

To identify structural determinants and regulatory components of the intestinal cytoskeleton and to study its functional contribution to intestinal physiology, we performed a mutagenesis screen using a reporter strain producing cyan fluorescent protein (CFP)-tagged intermediate filament protein IFB-2::CFP exclusively in the intestinal endotube (Hüsken et al., 2008). Using this strategy, we recently identified the novel intestinal filament organizer IFO-1, which acts as a structural component to localize the intermediate filament–rich endotube to the periluminal subapical cytoplasmic region of intestinal cells (Carberry et al., 2012). Here we characterize mutants of the MAP kinase 7 orthologue SMA-5, which has been linked to growth regulation (Watanabe et al., 2005), and show that sma-5 alleles induce the development of bubble-shaped invaginations of the apical plasma membrane together with the associated actin and modified intermediate filament cytoskeleton into the cytoplasm of intestinal cells.

RESULTS

SMA-5 mutations induce IFB-2::CFP–labeled cytoplasmic invaginations in the intestine

Allele kc1 was selected in a mutagenesis screen of IFB-2::CFP–expressing strain BJS2 (details in Carberry et al., 2012). Fluorescence microscopy of outcrossed homozygous strain BJ132 revealed that the circumferential localization of the IFB-2::CFP endotube was disrupted presenting multiple bubble-shaped IFB-2::CFP–positive protrusions into the apical cytoplasm along the entire length of the adluminal surface of all intestinal epithelial cells (Figure 1, A and B). These alterations were not detectable during embryogenesis (unpublished data) and larval development (Figure 1C) but emerged from early adulthood onward (Figure 1D), increasing in number throughout the intestine during aging (Figures 1B and 2, B, E, and H).

We used chromosomal and subchromosomal single-nucleotide polymorphism mapping to localize the kc1 mutation to the interval between 6.6 and 6.97 cM on the X chromosome, a region encompassing 94 protein-coding genes. The kc1-like phenotype was then mapped by bacterial feeding and microinjection of dsRNA to the sma-5 gene W06B3.2 (Figure 1E), which had been recently characterized by Watanabe and colleagues (2005). They showed that its mutation (allele n678) causes small body size despite unaltered cell numbers, slow growth, and abnormal intestinal granules. Aberrations of the intestinal cytoskeleton, however, were not investigated in this study. We therefore crossed the sma-5(n678) allele into the ifb-2::cfp reporter background. The resulting worms presented an even more severe phenotype of IFB-2::CFP distribution than those carrying the sma-5(kc1) allele, with many more invaginations in adults and already detectable invaginations in early larval stages (Figures 1F and 2, C, F, and I).

To demonstrate that a lack of functional SMA-5 is responsible for the kc1 phenotype, we performed rescue experiments with a fosmid construct that we obtained from the TransgeneOme Project.
FIGURE 2: Development of the sma-5 phenotype is age-dependent. IFB-2::CFP fluorescence (inverse presentation) was recorded 1 d (A–C), 2 d (D–F), and 4 d (G–I) after hatching. The percentage of animals showing a cytoplasmic invagination phenotype is shown at right. Wild-type animals were completely devoid of invaginations at all time points (A, D, G; 1 d: 0% [n = 0/16]; 2 d: 0% [n = 0/13]; 4 d: 0% [n = 0/21]), while a few sma-5(kc1) animals displayed scarce invaginations at 1 d (B; 9.10% [n = 2/22]). A substantial increase in number of affected animals and density of cytoplasmic invaginations occurred during aging (E, H; 2 d: 50.82% [n = 18/35]). Most animals carrying allele n678 presented cytoplasmic invaginations already 1 d after hatching (C; 94.12% [n = 31/33]), and 2 d after hatching (F; 2 d: 94.74% [n = 18/19]), leading to full penetrance by 4 d after hatching (I; 4 d: 100% [n = 28/28]). Scale bars: 20 μm in A–I; 10 μm in inset of F; 20 μm in all other insets.

sma-5(kc1) carries a point mutation in the region encoding a highly conserved catalytic serine–threonine kinase domain

The WormBase gene model (www.wormbase.org) of the sma-5 gene predicts four protein isoforms: a, b, c, and d. They give rise to polypeptides with a molecular weight of 56.7 kDa (a), 55 kDa (b), 57.6 kDa (c), and 51.3 kDa (d) and isoelectric points of 7.4, 6.61, 6.71, or 6.94, respectively. Further analysis based on RNAseq data suggests the appearance of alternative splice variants of isoform c (c1 and c2) and isoform d (d1 and d2) (Supplemental Figure S2). Of note, the cDNA corresponding to isoform a was used to successfully rescue the intestinal phenotype using the vha-6 promoter (Figure 3, D and D′).

A BLAST (Basic Local Alignment Search Tool) search revealed that SMA-5 orthologues are present in other nematodes including Cae- norhabditis remanei, Cae norhabditis japonica, Cae norhabditis briggsae, Pristionchus pacificus, and Caenorhabditis breneri with amino acid similarities of 99.2, 98.2, 94.9, 78.2, and 77.4%, respectively. More importantly, searches in the KEGG database (www.genome.jp/kegg) showed that SMA-5 orthologues are conserved throughout the
animal kingdom, including in the model organisms Drosophila melanogaster and Danio rerio (Supplemental Figure S3). The human SMA-5 orthologue still shows a similarity of 36% to the nematode counterpart. It encodes the 816 amino acid isoform 1 of mitogen-activated protein kinase 7 (BMK1/ERK5; ENSP00000311005).

Sequencing the entire smo-5 gene of kc1 animals showed that the gene contains a single point mutation (position 998 in CELE_W06B3.2a) resulting in a change of R125 (CGG) into H125 (CA C) (marked in yellow in Supplemental Figure S3). Protein domain analysis using the SMART-server (http://smart.embl-heidelberg.de) identified SMA-5 as a serine–threonine kinase with a typical catalytic domain located between amino acids 81 and 388 in isoform a. Remarkably, R125 is contained in a highly conserved sequence motif, which shows similarities to D. melanogaster (38.5%), D. rerio (40.4%), and Homo sapiens (42.3%). R125 is just three amino acids away from one of the essential and also fully conserved amino acids (E129; marked in blue in Supplemental Figure S3). This can be taken as an indication for dysfunctional kinase activity of the kc1-encoded SMA-5 mutant protein. In contrast, the smo-5(n678) allele contains a 226 base pair deletion of the 3' coding region of smo-5, leading to truncation of the last 75 amino acids in addition to a complete ~15 kb deletion of the downstream genes C49F5.3, C49F5.5, C49F5.6, and C49F5.7 (Watanabe et al., 2005).

**smo-5 mutants are small and have reduced brood size, slower larval development, and decreased life span**

Next we wanted to investigate the consequences of the altered intestine for worm growth, replication, development, and survival. The histogram in Figure 5A shows that smo-5(kc1) worms were smaller (1.11 ± 0.05 mm; n = 38) than the wild type (1.27 ± 0.06 mm; n = 54; p < 0.001) and that smo-5(n678) worms were even smaller (0.72 ± 0.10 mm; n = 37; p < 0.001). Furthermore, the number of progeny was significantly (p < 0.001) less in smo-5(kc1) (168 ± 29; n = 40) and smo-5(n678) (69 ± 22; n = 44) than in the wild type (209 ± 21; n = 50; Figure 5B). Increased embryonic lethality was not observed in the mutants (unpublished data), but development was considerably (p < 0.001) prolonged in the mutants (Figure 5C). Time of development at 18°C was 5.01 ± 0.49 d in the wild type (n = 269), and 7.36 ± 0.65 d in smo-5(kc1) (n = 181). In addition, a reduced life span was observed in both smo-5 alleles (kc1: 19 d; n = 468; n678: 17 d; n = 461) versus the wild type (25 d; n = 512; p < 0.001) (Figure 5D).

To demonstrate that the phenotype was caused by intestine-specific loss of SMA-5 function, we performed smo-5(RNAi) experiments in strain OLB11, which facilitates selective RNA interference (RNAi) in the intestine (Pilipiuk et al., 2009). These animals not only replicated the characteristic cytoplasmic invaginations in the intestine but also showed reduced growth, retarded development, and reduced brood size (Supplemental Figure S4). Conversely, SMA-5::EGFP expression in n678 mutants not only rescued the intestinal phenotype but also rescued body size (935.0 ± 10.42 μm; n = 46 in rescued worms vs. 1035 ± 14.63 μm; n = 41 in wild type and 603.4 ± 15.99 μm; n = 47 in n678 mutants; p < 0.0001). Taken together, the observed phenotypes are indicative of compromised food resorption.
sma-5 mutations induce an overall reorganization of the apical cytoskeleton in the intestine but do not perturb junction localization and integrity

Differential interference contrast microscopy revealed that the bubble-shaped structures bulged out from the intestinal lumen (arrows in Figure 6, B–D). These invaginations were much more frequent and pronounced in n678 than in kc1 mutants. The adjacent apical domain, however, was still inconspicuous (arrowheads in Figure 6, B–D). Luminal width was often enlarged, especially in n678 mutants (asterisks in Figure 6D). To find out whether these invaginations are connected to the intestinal lumen and whether they are surrounded by IFB-2, we performed feeding experiments with the membrane-impermeable dye Texas Red-dextran in IFB-2::CFP reporter strains (n = 50). The dye was restricted to the intestinal lumen in wild-type and mutant worms, demonstrating that the intestinal barrier remains intact. In addition, the dye filled all the luminal pockets that herniate into the cytoplasm in the kc1 (n = 50) and n678 mutants (n = 50; Figure 6, E–G″). These cytoplasmic invaginations were surrounded by IFB-2::CFP fluorescence, which often appeared to be discontinuous.

To examine the structural and topological integrity of the C. elegans apical junction (CeAJ), we performed immunofluorescence microscopy on isolated adult intestines with antibodies directed against the junctional MAGUK protein DLG-1 (Figure 7, A″–C″). The localization and continuity of immunostaining was unperturbed in the mutants presenting the characteristic ladder pattern. This result further supports the dextran-feeding experiments demonstrating that the intestinal barrier function is still fully intact. Next we wanted to study the effect of sma-5 mutation on other intermediate filament polypeptides in the intestine. Figure 7, A–C, shows that IFC-2 perfectly colocalizes with IFB-2 in both the wild-type and mutant intestines. To test, whether and how other components of the apical cytoskeleton are affected, we studied the distribution of F-actin. As expected, phalloidin staining showed apical F-actin enrichment next to IFB-2 immunoreactivity (e.g., Carberry et al., 2012). This codistribution was maintained in the mutants with F-actin staining in the IFB-2–positive cytoplasmic invaginations (Figure 7, D–F″). In the following set of experiments, we looked at the cytoskeletal linker ezrin–radixin–moesin C. elegans orthologue ERM-1, which links actin to the plasma membrane (Göbel et al., 2004; van Fürden et al., 2004; Fivet et al., 2007; Felhorn et al., 2010). As exemplified in Figure 7, H–I″, ERM-1 also localizes to the cytoplasmic invaginations of both sma-5 mutants. Taking these findings together, we conclude that the entire apical membrane domain is displaced into the cytoplasm of sma-5 mutants, and these invaginations remain in direct contact with the intestinal lumen.

The intestinal filament organizer IFO-1 acts additively with SMA-5

Because the recently characterized intestinal filament organizer IFO-1 plays a crucial role in correct localization of the subapical intermediate filament and actin cytoskeleton in the intestine (Carberry et al., 2012), we examined the distribution of IFO-1 in the sma-5 mutant background. As expected, IFO-1 codistributed closely with IFB-2 in the subapical intestinal cytoplasm (Figure 8, A–A″). It also codistributed in mature invaginations of sma-5(RNAi)-treated animals (Figure 8, B–B″). Slight differences between IFO-1 and IFB-2 distribution were, however, occasionally detectable, especially in smaller invaginations, where strong IFO-1 fluorescence was detectable without significant IFB-2 (Figure 8, B–B″ and Supplemental Figure S5). The findings indicate either that IFO-1 precedes cytoplasmic translocation of IFB-2 or that cytoplasmic invaginations occur at positions of a discontinuous, that is incomplete, IFB-2 network.

To further investigate the genetic relationship between sma-5 and ifo-1, we prepared double knockdowns. Supplemental Figure S6 shows that ifo-1(RNAi) in sma-5(kc1) induced both the sma-5–dependent cytoplasmic invaginations and the enrichment of IFB-2 at the CeAJ that is typically found in ifo-1 mutants. Junctional integrity remained intact, and no additional phenotype was detected. The additive nature of the phenotype indicates that the mutations act on intermediate filament network organization at least in part through separate pathways.

FIGURE 4: SMA-5::EGFP is detected throughout the entire intestine and weakly in restricted regions of the somatic gonad. The in vivo fluorescence pictures in A″–D″ (corresponding interference contrast images in A–D) and immunofluorescence pictures of dissected intestines detecting GFP (E–F″) show expression of an extrachromosomal sma-5::egfp-containing fosmid. Note that the fluorescence is restricted to the cytoplasm of enterocytes, with prominent apical enrichment in some instances (arrowheads in B) with no detectable expression in either pharynx (P) or gonad (Go) even after overexposure (E′ and F′). Occasionally, localized expression was noted in the somatic gonad (asterisks in D″, E″, and F″) Scale bars: 50 μm in A–D″; 25 μm in E″–F″.
SMA-5 is needed for structural maintenance of the intermediate filament–rich endotube and ordered arrangement of microvilli

Electron microscopy was performed to study luminal alterations at the ultrastructural level. In the wild-type situation (n = 3), the intestinal lumen, in transverse section, has a regular ellipsoid shape and is surrounded by evenly sized and regularly arranged microvilli of the brush border (Figure 9, A–C; see also Carberry et al., 2012; www.wormatlas.org). The intermediate filament–rich endotube appears as an electron-dense structure surrounding the lumen below the organelle-free terminal web (green arrowheads). It is anchored to the CeAJs at cell–cell borders (white arrowheads). When viewed in longitudinal section, kci and n678 mutants (Figure 9, D–I; n = 4 for kci; and n = 4 for n678) showed luminal pockets extending into the intestinal cytoplasm that were not observed in the wild type. The invaginations were still connected to the intestinal lumen, and no additional lumina were observed. These pockets are formed at transition zones where the endotube is considerably thinned (yellow arrowheads) or completely missing (red arrowheads). Overall local endotube thinning was observed in both mutant backgrounds, although it was more pronounced and combined with much larger gaps in n678. Local endotube thickening was not seen in kci but was quite pronounced in n678 (blue arrowheads). Taken together, these findings indicate that the continuity of the endotube is compromised in the mutant intestine, leading to cytoplasmic invaginations, and likely explains the reduced/absent decoration by IFB-2 (Figure 8, B–B″, and Supplemental Figure S5). Furthermore, the regular microvillar arrangement was considerably perturbed in several regions (e.g., Figure 9, I and L). Regular spacing and orthogonal protrusion of microvilli, which are so characteristic for a genuine brush border, were lost. Finally, the CeAJs were morphologically inconspicuous, supporting the observed functional integrity of the intestinal barrier (Figure 9, J–L).

SMA-5 activity affects phosphorylation of intermediate filament proteins

To test whether the observed structural alterations of the IF system are linked to altered phosphorylation of intermediate filament polypeptides, we performed two-dimensional gel electrophoresis and immunoblotting to detect changes in isoelectric points. Figure 10 shows results using anti–IFB-2 antibodies. In wild-type N2, a single isoelectric variant could be detected for the higher molecular weight isoform IFB-2a, while two isoelectric variants were visible for the lower molecular weight isoform IFB-2c with a major spot (2c and 2c″, respectively). Phosphatase treatment resulted in a shift of isoelectric points toward basic with the appearance of new immunoreactive signals labeled as 2a″ and 2c″p. A different pattern of IFB-2 immunoreactivity was observed in lysates obtained from sma-5(n678) worms with an overall reduction of isoelectric points and appearance of new signals in the more acidic part of the pH gradient (2a‴, 2a‴p, 2c‴p). Phosphatase treatment reversed this pattern toward more basic isoelectric variants. These data support the notion that intermediate filament polypeptides are phosphorylated and indicate that SMA-5 inactivation leads to increased intermediate filament phosphorylation. To examine whether this paradoxical effect might be mediated through altered ERM-1 phosphorylation, we performed immunoblots (Supplemental Figure S7). They show that the overall ERM-1 expression is reduced, while the fraction of phosphorylated ERM-1 remains unaltered in n678 mutants.

DISCUSSION

We provide genetic evidence that kinase activity is linked to intermediate filament network stability in the polarized simple epithelium of the C. elegans intestine by identifying the serine–threonine MAPK7 kinase orthologue SMA-5 as a key regulator of intermediate filament network organization. In sma-5 mutants, the intermediate filament protein IFB-2 is hyperphosphorylated rather than hypophosphorylated, as one might expect if IFB-2 was a direct target of SMA-5. Therefore it is more likely that SMA-5 activates another kinase or inhibits a phosphatase that could then act on intermediate filament protein IFB-2. Thus, alterations of the IF system are linked to alterations in intestinal morphology.

regular microvillar arrangement was considerably perturbed in several regions (e.g., Figure 9, I and L). Regular spacing and orthogonal protrusion of microvilli, which are so characteristic for a genuine brush border, were lost. Finally, the CeAJs were morphologically inconspicuous, supporting the observed functional integrity of the intestinal barrier (Figure 9, J–L).

SMA-5 activity affects phosphorylation of intermediate filament proteins

To test whether the observed structural alterations of the IF system are linked to altered phosphorylation of intermediate filament polypeptides, we performed two-dimensional gel electrophoresis and immunoblotting to detect changes in isoelectric points. Figure 10 shows results using anti–IFB-2 antibodies. In wild-type N2, a single isoelectric variant could be detected for the higher molecular weight isoform IFB-2a, while two isoelectric variants were visible for the lower molecular weight isoform IFB-2c with a major spot (2c and 2c″, respectively). Phosphatase treatment resulted in a shift of isoelectric points toward basic with the appearance of new immunoreactive signals labeled as 2a″ and 2c″p. A different pattern of IFB-2 immunoreactivity was observed in lysates obtained from sma-5(n678) worms with an overall reduction of isoelectric points and appearance of new signals in the more acidic part of the pH gradient (2a‴, 2a‴p, 2c‴p). Phosphatase treatment reversed this pattern toward more basic isoelectric variants. These data support the notion that intermediate filament polypeptides are phosphorylated and indicate that SMA-5 inactivation leads to increased intermediate filament phosphorylation. To examine whether this paradoxical effect might be mediated through altered ERM-1 phosphorylation, we performed immunoblots (Supplemental Figure S7). They show that the overall ERM-1 expression is reduced, while the fraction of phosphorylated ERM-1 remains unaltered in n678 mutants.

DISCUSSION

We provide genetic evidence that kinase activity is linked to intermediate filament network stability in the polarized simple epithelium of the C. elegans intestine by identifying the serine–threonine MAPK7 kinase orthologue SMA-5 as a key regulator of intermediate filament network organization. In sma-5 mutants, the intermediate filament protein IFB-2 is hyperphosphorylated rather than hypophosphorylated, as one might expect if IFB-2 was a direct target of SMA-5. Therefore it is more likely that SMA-5 activates another kinase or inhibits a phosphatase that could then act on intermediate filaments. We describe phenotypic changes in the two mutant sma-5 alleles, n678 and kc1. The more severe phenotype in n678 mutants is linked to a mutation in a single codon within the catalytic domain that may render the enzyme less active but not completely dysfunctional.
Our study extends previous work that first identified and characterized worms carrying the n678 mutation (Watanabe et al., 2005, 2007). However, these authors did not describe the drastic rescue in cytoskeletal organization and luminal defects that we characterize here. Furthermore, our data are in contrast with the reported rescue of the sma-5 phenotype by expression in the hypodermis. Instead, we show a complete rescue of the sma-5 phenotype by intestine-specific reintroduction of a sma-5 reporter. In accordance, we find a phenocopy of the sma-5 phenotype, that is, reduced body length, growth retardation, reduced brood size, and shortened life span upon intestine-specific sma-5(RNAi). We therefore conclude that the sma-5 phenotype is caused by intestine-specific SMA-5 function.

In sma-5 mutants, a morphologically normal subapical cytoskeleton forms around the lumen of the intestine initially but becomes progressively disorganized over time. We interpret the incremental appearance of the pathological phenotype as a consequence of kinase dysfunction resulting in impaired resilience of the endotube, which manifests as cytosplasmic invaginations upon prolonged and increasing wear and tear. However, the endotube in sma-5 mutants appears to be fragile and eventually ruptures, perhaps because of stress from normal wear and tear or because of growth during development. The worm intestine seems to be sensitive to stress, and invaginations and luminal dilation occur in worms subjected to challenges such as microbial infection (Estes et al., 2011) or exposure to fungal lectins (Stutz et al., 2015) or pore-forming toxins (Los et al., 2011). In fact, the intestinal filament organizer IFO-1 is up-regulated in response to pore-forming toxins, and this up-regulation requires another MAP kinase, KGB-1 (Kao et al., 2011). In support of a protective role for the SMA-5 MAP kinase, the vertebrate homologue MAPK7 is activated by oxidative stress and hypo-osmolarity (Abe et al., 1996; Chao et al., 1999).

IFO-1 is a critical component of the organization of intermediate filaments in the intestine. During embryogenesis, IFO-1 accumulates at the apical plasma membrane before localization of intermediate filaments (Carberry et al., 2012). Moreover, in ifo-1 mutants, intermediate filaments collapse onto the CeAJ. In sma-5 mutants, sites of IFO-1 delamination seem to precede the subsequent herniation of the intermediate filament protein IFB-2 and the lumen of the intestine. We stress, however, that the functions of IFO-1 and SMA-5 are separable, rather than being organized in a simple pathway. Loss of IFO-1 leads to intermediate filament accumulation at junctions, whereas loss of SMA-5 leads to a weakening of the intermediate filament–rich endotube leading to cytoplasmic invaginations. As expected, we find that sma-5 and ifo-1 phenotypes are additive in double knockdowns. Furthermore, loss of SMA-5 is coupled to intermediate filament hyperphosphorylation, whereas loss of IFO-1 does not lead to changes in intermediate filament phosphorylation (F.G., unpublished observations). Thus, even though IFO-1 is a potential target of kinases (phosphorylation site database, www.phosida.com), there must be additional SMA-5 targets whose phosphorylation affects intermediate filament phosphorylation and overall apical domain stability. A suppressor screen of the sma-5 mutants could possibly identify the pathway that links SMA-5 to intermediate filament phosphorylation and network organization. It may also help to understand how and why SMA-5 dysfunction results in two opposing morphologies, namely endotube thinning and endotube thickening. It is possible that phosphorylation of different targets by SMA-5 may be important for network formation and network disassembly.

Our data suggest that the endotube itself becomes organized in a trilaminar structure, with an actin network closest to the plasma membrane anchoring the microvilli, followed by an IFB-2 intermediate filament layer and an IFO-1 layer below. First, we sometimes see that the IFO-1 layer has delaminated and buckled, whereas the IFB-2 layer is still intact. Second, we observe that the actin cytoskeleton is also disrupted in advanced endotube hernias. The observation that the displacement of actin, the actin-binding protein ERM-1,
IFB-2, and IFC-2 occurs in concert and coincident with the formation of dextran-filled invaginations suggests that the intermediate filament network provides a major scaffolding on which the entire apical membrane domain rests. The existence of cross-bbridges among the components in C. elegans is also supported by the observation of similar invaginations in act-5(RNAi), act-5(ok1397), erm-1(RNAi), and ifc-2(RNAi) intestines (Göbel et al., 2004; Hüsen et al., 2008; Saegusa et al., 2014). In accordance, ultrastructural and molecular links have been described among these components in mice (Hirokawa et al., 1982; Grimm-Günter et al., 2009).

Previous studies in cultured epithelial cells have indicated a role for kinase signaling in epithelial intermediate filament network organization. The ratio of filamentous to soluble keratin correlates with keratin phosphorylation in most, though not all, instances (Chou and Omary, 1993; Liao et al., 1996; Strnad et al., 2002). Furthermore, inhibition of either tyrosine phosphatases or serine–threonine phosphatases resulted in rapid keratin network disruption (Strnad et al., 2001, 2002). Specifically, an involvement of the p38 MAP kinase has been demonstrated in phosphatase inhibitor–induced network disassembly into granular aggregates (Ku et al., 2002; Wöll et al., 2007). In accordance, stimulation of p38 activity induced network disorganization, leading to the formation of large granules containing phosphorylated keratins (Wöll et al., 2007). JNK and p38 MAP kinase–dependent keratin phosphorylation has been described for several stress paradigms such as osmotic imbalance and heat and chemical stress (D’Alessandro et al., 2002; Ku et al., 2002; Wöll et al., 2007). It was further shown that cooperation between p38 MAP kinase and MAPKAP kinase MK2/3 is responsible for keratin phosphorylation in intestinal HT29-MTX cells (Menon et al., 2010). Remarkably, MK2-deficient mice become less sensitive to dextran sodium sulfate (DSS)-induced colitis (Li et al., 2013). This situation is analogous to that encountered in our sma-5 mutants. We suggest that the protective effect against stress is mediated in both instances by reduced intermediate filament phosphorylation resulting in a more resilient filament network. Furthermore, similar mechanisms may act in other cell systems. Thus it has been demonstrated that tension induces a mechanotransduction pathway in the C. elegans hypodermis, whose output is increased intermediate filament phosphorylation (Zhang et al., 2011). It also involves a kinase (PAK-1) whose activity is stimulated by a hemidesmosomal mechanosensor acting through hemidesmosomal adaptor proteins and the Rac GTPase CED-10. It will be interesting to find out whether similar pathways involving SMA-5 exist in the C. elegans intestine.

The evolutionary conservation of the subapical distribution of intermediate filaments anchored to the apical junctional complex, either in the form of the prominent endotube in C. elegans or as a dense network below the terminal web in Isotumurus maculatus (Mencarelli et al., 2011), to mouse (Hirokawa et al., 1982) and man.
support for a function of intermediate filaments in intestinal barrier formation and its regulation by phosphorylation. Thus interleukin-6 (IL-6) activity evoked increasing phosphorylation of keratins 8 and 18 coincident with subapical intermediate filament accumulation in cultured colon carcinoma–derived Caco2-BBE cells (Wang et al., 2007). In accordance, IL-6 knockout mice presented with reduced keratin 8 levels and showed increased intestinal permeability after administration of dextran sulfate sodium (DSS) (Wang et al., 2007). The relationship between intestinal barrier function and keratin phosphorylation is also suggested by the work of Tao et al. (2006), who demonstrated that hypo-osmosis induced site-specific dephosphorylation of keratin 8 in HT29 cells, whereas hyper-osmosis induced keratin 8 hyperphosphorylation. These observations are in contrast to reports in the same study noting keratin hyperphosphorylation in human HRT18 and Caco2 cells and in ex vivo colon cultures upon hypo-osmosis. But they also underscore the importance, though presently poorly understood relevance, of intermediate filament phosphorylation in different stress paradigms.

Taking these findings together, we conclude that intermediate filaments are crucial ingredients for the maintenance of the C. elegans intestinal tube, which is an important prerequisite for efficient food uptake. It is likely that they fulfill similar functions in other lumen-containing epithelial structures such as the excretory cells in C. elegans (Kolotuev et al., 2013).

**FIGURE 8:** Intestine-specific **sma-5**(RNAi) animals and sma-5 mutants develop IFB-2- and IFO-1–positive cytoplasmic invaginations. (A–C) Antibody staining detecting IFB-2 and IFO-1 in the dissected adult intestine of intestine-specific RNAi strain OLB11 (A–A′), OLB11 treated with sma-5(RNAi) (B–B′), and sma-5(n678) mutants (C–C′). (D–F) In vivo fluorescence detection of IFB-2::CFP and IFO-1::YFP (inverted presentation in D, D′; E, E′, F, F′; corresponding interference contrast images in D″, E″, F″, respectively) in wild-type strain BJ276 (WT; D–D″) and sma-5(ks1) animals of strain BJ277 (E–F″). The images depict the characteristic apical colocalization of IFB-2 and IFO-1 that is maintained in the cytoplasmic invaginations forming in the mutant backgrounds. Note that invaginations are usually marked by both (arrowheads), although occasionally IFO-1–positive invaginations lack IFB-2 (e.g., arrows in B–B′). Scale bars: 10 μm in A–C′; 20 μm in D–F′; 10 μm in insets of E–E′; 20 μm in insets of F–F′; 5 μm in insets of B–B′.

(Mooseker, 1985; Carboni et al., 1987) can be taken as evidence for the functional importance of this arrangement. The small body size, reduced brood size, developmental retardation, and reduced life span observed in sma-5 mutants (this study) and ifo-1 mutants (unpublished data; Carberry et al., 2012) all strongly support this notion. In addition, mechanical functions have been ascribed to intestinal intermediate filaments (Jahnel et al., 2016) and keratin mutations have been linked to intestinal inflammation in mice lacking keratins (Baribault et al., 1994; Habtezion et al., 2005). Interestingly, keratin polymorphisms have been associated with intestinal bowel disease in human patients (Owens and Lane, 2004; Owens et al., 2004; Zupancic et al., 2014). In vitro observations provide further evidence of a functional importance of intermediate filaments in intestinal barrier formation and its regulation by phosphorylation. Thus interleukin-6 (IL-6) activity evoked increasing phosphorylation of keratins 8 and 18 coincident with subapical intermediate filament accumulation in cultured colon carcinoma–derived Caco2-BBE cells (Wang et al., 2007). In accordance, IL-6 knockout mice presented with reduced keratin 8 levels and showed increased intestinal permeability after administration of dextran sulfate sodium (DSS) (Wang et al., 2007). The relationship between intestinal barrier function and keratin phosphorylation is also suggested by the work of Tao et al. (2006), who demonstrated that hypo-osmosis induced site-specific dephosphorylation of keratin 8 in HT29 cells, whereas hyper-osmosis induced keratin 8 hyperphosphorylation. These observations are in contrast to reports in the same study noting keratin hyperphosphorylation in human HRT18 and Caco2 cells and in ex vivo colon cultures upon hypo-osmosis. But they also underscore the importance, though presently poorly understood relevance, of intermediate filament phosphorylation in different stress paradigms.

Taking these findings together, we conclude that intermediate filaments are crucial ingredients for the maintenance of the C. elegans intestinal tube, which is an important prerequisite for efficient food uptake. It is likely that they fulfill similar functions in other lumen-containing epithelial structures such as the excretory cells in C. elegans (Kolotuev et al., 2013).

**MATERIALS AND METHODS**

**DNA constructs**

Fosmid WRM0633B_G09(pRedFlp-Hgr) (sma-5[26688]:S0001_pR6K_Amp_2xTY1ce_EGFP_FRT_rpsl_neo_FRT_3xFlag)dFRT:unc-119-Nat (here referred to as fosmid 3170) was obtained from the TransgeneOme Project of the Max Planck Institute of Molecular Cell Biology and Genetics (Sarov et al., 2006; TransgeneOme Project, https://transgeneome.mpi-cbg.de/transgeneomics/index.html). pWD553 was made by first cloning the sma-5 cDNA into the PstI-Xmal sites of plasmid pPiB-2:cfp (1759; Hüsken et al., 2008). Next the ifb-2 promoter was replaced by the vha-6 promoter. This was done with a Gibson reaction (Gibson et al., 2009) of two fragments. The first fragment was a PstI-HindIII digest. The second was a PCR of the vha-6 promoter using primers TAAACACTTGGAAATGAAATAAGCTTaaagtatactattctattactgactactttgtgta and TGTGGAGGAGACATCTGCAGtttttatgggcttttgtagtttagtttcgcctg. The PCR template was pML25 [vha-6p]. pWD554 was made by replacing the cfp coding sequence and the unc-54 3′-untranslated region (UTR) of pWD553 with the let-858 3′ UTR. This was done with a Gibson reaction (Gibson et al., 2009) of...
FIGURE 9: Luminal perturbations, disordered microvilli, and endotube alterations with local gaps are present in the intestine of sma-5 mutants. The electron micrographs are taken from wild type (transverse sections, A–C, J), sma-5(kc1) (longitudinal sections, D–F, K), and sma-5(n678) mutants (longitudinal sections, G–I, L). Differently sized luminal invaginations into the cytoplasm of enterocytes are seen in both mutants (D–H). Note that the endotube layer is indistinguishable from that of the wild type in some regions (green arrowheads) but is drastically altered in other regions. In sma-5(kc1) local endotube thinning (yellow arrowheads) and endotube gaps (red arrowheads) are observed. In sma-5(n678), localized and extensive endotube thickening (blue arrowheads) and thinning (yellow arrowheads) with complete endotube loss (red arrowheads) are frequent. Note also that loss of endotube and endotube thinning coincide with the rim of cytoplasmic invaginations (E, F, and H). In addition, the brush border (B) is irregular in many regions, with variable spacing and orientation (e.g., I and L). The CeAJ appears unperturbed (white arrowheads in A–C, J–L) and is still associated with the material of the endotube. L, lumen; Y, yolk granule; F, lipid droplet. Scale bars: 2 μm in A, D, and G; 500 nm in B–C, E–F, and H–L.
two fragments. The first was a SmaI-Spel digest of pWD553. The second was a PCR of the let-858 UTR using the primers ATTGCG-CAGCAACCGGGTAAATCGAGCCACAGTCTGTAattttt and GGGCGTTAGCCGCGAAATCAACAGCAGAACATTCCAGG and pPDA126 (Watanabe et al., 2011) as a template. pWD555 was made by adding three native introns into the sma-5 cDNA. This was done using a Gibson reaction (Gibson et al., 2009) of two fragments. The first was a BamHI-BglII digest of pWD554, and the second was a PCR from worm genomic DNA using primers tcttcatgctgatcaattcttt and catgctgatcaattctttt. The resulting PCR fragment was digested with BamHI and SpeI and inserted into the pPD126 plasmid, which was subsequently transformed into E. coli DH10B to produce Smal to 4 kb. The resulting plasmid was named pWD555.

C. elegans strains

Wild-type Bristol strain N2 and Hawaiian strain CB4856 were obtained from the Caenorhabditis Genetics Center (CGC; University of Minnesota, Minneapolis, MN). Strain BJ52 kcels21(ifb-2p::ifb-2::cfp)V was recently described (Hüsken et al., 2008; for chromosomal mapping, see Hüsken, 2008). sma-5 mutant strains carrying allele kc1 were BJ132 sma-5(kc1)X;kcels21(ifb-2p::ifb-2::cfp)V and BJ141 sma-5(kc1)X. Strain FK312 sma-5(n678)X (Watanabe et al., 2007) was provided by the CGC. It was crossed with BJ49 kcels6(ifb-2p::ifb-2::cfp)V (Hüsken et al., 2008; for chromosomal mapping, see Hüsken, 2008) to obtain strain OLB18 sma-5(n678)X;kcels6(ifb-2p::ifb-2::cfp)V. BJ276 kcels30(ifo-1p::ifo-1::yfp;myo-3p::mCherry::unc-54)]; kcels21(ifb-2p::ifb-2::cfp)V were both generated in one step by crossing BJ132 with BJ186 kcels30(ifo-1p::ifo-1::yfp;myo-3p::mCherry::unc-54)]. Animals were generated by microinjection of fosmid 3170 into the gonad of DP38 unc-119(ed3) animals (provided by the CGC) to obtain strain BJ263 kcEx73(pRedFlip-Hgr)(sma-5[26688]; S0001_pR6K_Amp_2xTY1ce_EGFP_FRT_rpsl_neo_FRT_3xFlag)dFRT::unc-119-Nat) producing SMA-5::EGFP. Rescue strain BJ269 sma-5(kc1)X;kcEx73(pRedFlip-Hgr)(sma-5[26688]; S0001_pR6K_Amp_2xTY1ce_EGFP_FRT_rpsl_neo_FRT_3xFlag)dFRT::unc-119-Nat) was generated by microinjection of fosmid 3170 into BJ141 sma-5(kc1)X animals. Rescue strains BJ300/301 sma-5(n678)X; kcEx75[va-6p::sma-5;myo-2p::gfp::H2B] were generated by microinjection of plasmid pWD555 and pCFJ770 [myo-2p::gfp::H2B] into OLB18 animals. Microinjection of plasmid 1772 [ifb-2p::ifb-2::cfp] (Hüsken et al., 2008) into the gonad of strain EC668 kcEx41[unc-119(+); ifa-1a::gfp]; unc-119(ed3)III (Karabinos et al., 2003) yielded strain BJ37 kcEx41[unc-119(+); ifa-1a::gfp]; unc-119(ed3)III. Maintenance and propagation of strains was done as previously described (Brenner, 1974).

RNAi

RNAi by feeding was performed as previously described (Hüsken et al., 2008) with minor modifications. Nematode growth medium (NGM) plates contained 100 μg/ml ampicillin, 12.5 μg/ml tetracycline, and 2 mM isopropl β-D-thiogalactopyranoside (IPTG). Plasmid clones for RNAi were either taken from the Ahinger RNAi library (Geneservice, Cambridge, UK) or obtained by

**FIGURE 10:** Two-dimensional immunoblot analysis of IFB-2 detects SMA-5–dependent phosphorylation. The picture shows immunoblots of polypeptides obtained from total worm lysates that were separated by two-dimensional isoelectric focusing gel electrophoresis (pH gradient of second dimension indicated on top) and reacted with monoclonal anti–IFB-2 antibodies. The higher magnifications at right depict details of the different IFB-2 isoforms that were detected. They differ in size (larger a and smaller c variant) and isoelectric points as a consequence of phosphorylation (+P, −P). Note that, at steady state, one a variant (denoted 2a) and two c variants, that is, a major spot denoted as 2c and a minor spot denoted as 2c+1P, are visible in the wild-type N2 background. As expected, phosphatase treatment leads to a shift to more basic isoelectric points (2a+1P and 2c+1P). In contrast, isoelectric points are shifted toward acidic in the sma-5(n678) background, with new spots at 2a+1P, 2a+2P, and 2c+2P. Again, phosphatase treatment shifts the variants toward the nonphosphorylated positions. Indication of molecular weight in kilodaltons.
cloning gene sequences of at least 500 base pairs containing a minimum of one coding exon into the feeding vector L4440 (Addgene) followed by chemical transformation into RNAsell-deficient HT115 Escherichia coli. Liquid overnight cultures in Luria broth with 100 μg/ml ampicillin and 12.5 μg/ml tetracycline were supplemented with 7 μl/ml 1 M IPTG before plates were inoculated with a volume of 300 μl each. After overnight incubation at room temperature, 10–20 L4 larvae were added; this was followed by incubation at 15°C or 18°C. After 48 h, adult grown animals were transferred to new plates and incubated as before until F1 progeny could be analyzed. Alternatively, RNAi by microinjection was performed. To this end, dsRNA was first amplified in vitro using the MAXScript T7 Kit (Ambion, Austin, TX) and then injected into L4 larvae using the inverse Leica DM IRB microscope (Leica, Wetzlar, Germany). Injected animals were subsequently incubated for 24 h at 20°C on normal NGM plates and transferred onto new plates for examination of F1 progeny.

**Isolation and identification of sma-5 mutants**

BJ52 kcls-2[ifb-2::ifb2-::cfp]V animals were subjected to chemical mutagenesis by incubating adult worms with 47 mM ethyl methane sulfonate for 4 h at room temperature. F2 progeny corresponding to 10,000 haploid genomes were screened for alterations of IFB-2::CFP fluorescence. Isolated animals were backcrossed five times with N2 to obtain strain BJ132 sma-5(kc1)X; kcls-2[ifb-2::ifb2-::cfp] V. Further identification of the mutated gene was done by single-nucleotide polymorphism mapping (Davis et al., 2005; Carberry et al., 2012) and RNAi targeting of the remaining 94 candidate genes within the mapped region. An RNAi screen was performed by bacterial feeding (Ahringer library) starting either with L1 or L4 larva of strain BJ52 at 18°C or 20°C, resulting in down-regulation of post-embryonic or embryonic gene function, respectively. In some instances, RNAi by microinjection of dsRNA was also performed, when appropriate feeding clones were not available. Animals were screened for a copy of the sma-5(kc1) phenotype using a fluorescence binocular.

**Immunostaining and fluorescence labeling**

For immunohistology, animals were dissected in phosphate-buffered saline on a poly-L-lysine–coated glass slide; this was followed by mounting a coverslip on top, removing excessive fluid, and freezing the sample in liquid nitrogen. The coverslip was then blasted off, resulting in permeabilization of the cuticle. Samples were then fixed by incubation at −20°C for first 10 min in methanol and then for 20 min in acetone, followed by incubation in a graded ethanol series (5 min in 90% ethanol at −20°C, 5 min in 60% ethanol at −20°C, and 5 min in 30% ethanol at room temperature). After a final wash for 10 min in TBST, samples were blocked for 1–2 h at room temperature in Roti-Block (Roth) and 5 min at 90°C. Proteins were separated in a 10% SDS polyacrylamide gel, and transferred onto polyvinylidene difluoride membrane. For immunostaining, antibodies dissolved in blocking solution (1% [wt/vol] nonfat milk powder [Roth, Karlsruhe, Germany], 1% [wt/vol] bovine serum albumin, and 0.02% [wt/vol] sodium azide) were incubated at 4°C overnight. Following a 10 min wash in TBST, samples were incubated with secondary antibodies dissolved in blocking solution for 2 h at room temperature. After a final wash for 10 min in TBST, samples were embedded in Mowiol 4–88 (Sigma, St. Louis, MO) supplemented with DABCO (Roth) and covered with a glass coverslip. The following primary antibodies were used: guinea pig anti-IFO-1 (1:100; Carberry et al., 2012), guinea pig anti-IFC-2 (1:10; Karabinos et al., 2002), rabbit anti-DLG-1 (1:200; Segbert et al., 2004), rabbit anti-ERM-1 (1:200; van Fürden et al., 2004), mouse monoclonal anti–IFB-2 (MH33, 1:200; Francis and Waterston, 1985), rabbit anti–GFP (1:1000; Invitrogen, Carlsbad, CA), and mouse monoclonal anti–AJM-1 (MH27, 1:200; Francis and Waterston, 1985). Secondary antibodies used at 1:200 dilution were Cy2-, Cy3-conjugated affinity-purified anti-mouse immunoglobulin G (IgG; Rockland, Limerick, PA), Alexa Fluor 488–conjugated affinity-purified anti-mouse IgG (Invitrogen), Alexa Fluor 555–conjugated affinity-purified anti-mouse IgG (Invitrogen), Dylight488- and Cy3-conjugated affinity-purified anti–guinea pig IgG, Cy2-, Cy3-, Cy5-conjugated anti–rabbit IgG (Jackson ImmunoResearch Laboratories, West Grove, PA), and Alexa Fluor 488–conjugated affinity-purified anti-rabbit IgG (Invitrogen). Actin filaments were stained by Alexa Fluor 546–phaloidin (Molecular Probes, Eugene, OR).

To label the intestinal lumen and to check for intestinal tightness, young adults were incubated on agar plates containing 100 μl of 0.3% (wt/vol) Texas Red–conjugated dextran (10,000 MW; Molecular Probes) in the presence of OP50 bacteria at room temperature for 24 h. They were subsequently washed three times in M9 medium before being imaged.

**Microscopy**

Microscopy was performed with confocal laser-scanning microscopes (LSM 510 META and LSM 710, Zeiss; Jena, Germany; TCS SP5; Leica), a Zeiss Apotome fitted with a Zeiss AxioCamMRm camera, and a Zeiss AxioPlan 2 fitted with an ORCA-ER camera (Hamamatsu, Herrsching, Germany). For electron microscopy, worms were cryofixed by rapid high-pressure freezing with the help of a Leica EM Pact high-pressure freezer. For each genotype, at least 10 samples, each consisting of 5–15 worms, were fixed. Quick-freeze substitution was done using two alternative fixatives: 1) 1% OsO4, 0.2% uranyl acetate in aceto- n, and 2) 1% OsO4, 0.5% uranyl acetate, and 5% H2O in acetone. Embedding into epoxy resin was performed as previously described (McDonald and Webb, 2011). Following quick-freeze substitution, 50 nm transverse and longitudinal ultrathin sections of the worms were prepared with a Leica UC6/FC6 ultramicrotome, contrasted for 10 min each in 1% uranyl acetate in ethanol followed by Reynolds lead citrate. Sections were viewed at 100 kV with a Hitachi H-7600 transmission electron microscope (Tokyo, Japan).

**Immunoblotting**

For each assay, 60 adult worms of the wild type or 120 sma-5(n678) mutant animals were handpicked, transferred into 30 μl dH2O, and immediately frozen at −80°C. After quick thawing, samples were sucked up and down through a 30G hypodermic syringe (BD Medical, Heidelberg, Germany) three times. Subsequently, 7.5 μl of 5x Laemmli loading buffer was added, and samples were incubated for 5 min at 90°C. Proteins were separated in a 10% SDS polyacrylamide gel, and transferred onto polyvinylidene difluoride membrane by wet-tank blotting at 100 V for 60 min. The membranes were blocked for 1–2 h at room temperature in Roti-Block (Roth) and then incubated with primary antibodies in Roti-Block at 4°C overnight. Antibodies against total ERM-1 (murine monoclonal antibodies from the Developmental Studies Hybridoma Bank [DHSB, Iowa City, IA]; Hadwiger et al., 2010) were diluted 1:1000, against phosphorylated ERM-1 (rabbit monoclonal antibodies ab76247 from Abcam, Cambridge, UK) 1:500, and against actin (rabbit polyclonal antibodies A2066 from Sigma) 1:1000. Three 10 min washings with TBST (20 mM Tris(hydroxymethyl)-aminomethane, 0.15 M NaCl, 0.1% Tween 20 [vol/vol], pH 7.6) ensued. Incubation with secondary antibodies (goat anti-mouse IgG antibodies and goat anti-rabbit IgG antibodies coupled to horseradish peroxidase from DAKO

Figure S1: Down regulation of *sma-5* does not interfere with pharyngeal IFA-1 and hypodermal IFB-1 localization but induces perturbations in IFB-2 distribution of young adult worms.

*sma-5(RNAi)* in strain BJ37 simultaneously expressing IFA-1::GFP (false red color) and IFB-2::CFP (false green color) does not interfere with the apicobasal bundles of IFA-1::GFP in the pharyngeal marginal cells that are typically found in wild-type worms (B), while IFB-2::CFP is not any more restricted to the subapical domain but surrounds large cytoplasmic invaginations (arrow) protruding from the dilated apical lumen (A). Similarly, *sma-5(RNAi)* does not interfere with the apicobasal distribution of IFB-1::GFP reporters connecting apical and basal hemidesmosomes in the hypodermis of strain CZ3464 (C) compared to control animals (D). Arrowheads in C and D indicate the excretory canal. Scale bars: 20 µm in A-D.

Figure S2: Multiple SMA-5 isoforms are predicted from the genomic sequence. Protein-coding exons are shown in blue, non-coding exons in grey and introns as thin black lines. The predicted variants differ with respect to their amino- and carboxytermini. In addition, alternative splice variants are depicted for isoforms c and d. The position of the point mutation in allele *kc1* is marked by the red arrowhead; the start of the deletion in allele *n678* encompassing the last exon of the *sma-5* gene is also shown. The insertion site of the EGFP-encoding *egfp* cDNA at the 3'-end of the protein-coding sequence in the rescue fosmid is demarcated. Note, that it is joined in frame at the carboxyterminus of isoforms a, c2 and d1 but would result in a small carboxyterminal deletion in isoforms b, c1 and d2. A cDNA encoding isoform a including three introns was used to prepare the intestine-specific rescue construct *vha-6p::sma-5* (pWD555). The scale bar at the top shows the relative position of the *sma-5* gene fragments on the X-chromosome in units of kb.
Figure S3: The predicted catalytic domain of SMA-5 is evolutionary conserved and contains a R125→H125 mutation in kc1.

A comparison of the predicted catalytic domains of SMA-5 (isoform a; CELE_W06B3.2a) and its orthologs in Drosophila melanogaster (Dmel.CG5475), Danio rerio (dre:541323) and Homo sapiens (hsa:5598) is shown (nomenclature taken from the KEGG database (http://www.genome.jp/kegg)). Asterisks below denote amino acids that are identical and : demarcate conserved amino acids that score > 0.5 in the Gonnet PAM 250 matrix. Amino acid groups are color-coded: blue, acidic; magenta, basic - H; green, hydroxyl + sulfhydryl + amine + G; red; small (small + hydrophobic (including aromatic -Y)). The relative amino acid position is given at the right for the last amino acid in each line. The G→A point mutation in kc1 at nucleotide position 998 of predicted isoform a (CELE_W06B3.2a) leads to a replacement of conserved R125 (yellow, boxed) by H125. The mutation is located within the predicted catalytic domain in a highly conserved sequence motif, which shows similarities to D. melanogaster (38.5%), D. rerio (40.4%) and H. sapiens (42.3%) and is adjacent to one of the crucial catalytic and also conserved amino acids (marked in blue).
Figure S4: Intestine-specific downregulation of *sma-5* RNA copies the phenotype of *sma-5(kc1)* and *sma-5(n678)* mutants.

The histograms show that *sma-5(RNAi)* in strain OLB11 leads to a significantly reduced growth (p<0.0001) as measured by reduced body length after 3 days (A; 524.5 ± 8.489 µm [n=100] in treated animals versus 756.2 ± 9.978 µm [n=73] in the wild type) and 4 days (B; 687.7 ± 11.50 µm [n=73] in treated animals versus 998.5 ± 13.50 µm [n=37] in the wild type) of RNAi treatment, significantly increased time of development (C; 5.585 ± 0.152 days; n=82 in treated animals versus 3.547 ± 0.041 days; n=172 in the wild type; p<0.0001) and reduced progeny (D; 98.42 ± 14.79; n=24 in treated animals versus 181.8 ± 9.615; n=24 in the wild type; p<0.001). For comparison see Fig. 5.
Figure S5: Some IFO-1-positive invaginations contain little or no IFB-2. The fluorescence images show antibody staining of *sma-5*(RNAi)-treated OLB11. Note that some of the IFO-1-positive invaginations lack significant IFB-2 immunolabel (boxed areas; arrow). Scale bars: 10 µm in A-A″, 5 µm in insets.
Figure S6: The *sma-5* and *ifo-1* mutant phenotypes are additive.
The fluorescence micrographs (inverse presentation) depict the distribution of IFB-2 as assessed by reporter IFB-2::CFP in *sma-5(kc1)* strain BJ132 without (A-A''; n=20) and with *ifo-1(RNAi)* (B-B''; n=10). The worms were fed with Texas Red-dextran for 12 hours prior to imaging. Note that the dextran fluorescence is retained within the IFB-2-lined lumen and cytoplasmic invaginations in both situations (A'', B'') demonstrating that the intercellular junctional seal remains intact. The images further show that animals lacking IFO-1 and wild-type SMA-5 present both, IFB-2-positive cytoplasmic invaginations (arrowheads B-B'') typically found in *sma-5* mutants and junctional collapse of IFB-2 (arrows B-B'), which is characteristic for *ifo-1* mutants. Scale bars: 20 µm.
Figure S7: The level but not the fraction of phosphorylated ERM-1 is reduced in \textit{sma-5(n678)} mutants.

The immunoblots at left show the reaction of antibodies directed against total ERM-1 (top) and phosphorylated ERM-1 (phospho-ERM-1; bottom) in the wild type (WT) and \textit{sma-5(n678)} mutants. The same blots were stained with actin antibodies for control (lower parts). The position of co-electrophoresed size markers are shown in kDa at left. The results of immunosignal quantification are depicted at right. Note that the overall expression level of ERM-1 is reduced in the mutant background. The fraction of phosphorylated ERM-1, however, remains almost the same (71\% in WT versus 67\% in \textit{sma-5(n678)}).
