(Received 20 April 2017; published 31 July 2017)

In this paper, we present a calculation of the $\gamma + j$ process at next-to-next-to-leading order (NNLO) in QCD and compare the resulting predictions to 8 TeV CMS data. We find good agreement with the shape of the photon $p_T$ spectrum, particularly after the inclusion of additional electroweak corrections, but there is a tension between the overall normalization of the theoretical prediction and the measurement. We use our results to compute the ratio of $Z(\to e^+e^-) + j$ to $\gamma + j$ events as a function of the vector boson transverse momentum at NNLO, a quantity that is used to normalize $Z(\to \nu\bar{\nu}) + j$ backgrounds in searches for dark matter and supersymmetry. Our NNLO calculation significantly reduces the theoretical uncertainty on this ratio, thus boosting its power for future searches of new physics.

DOI: 10.1103/PhysRevD.96.014037

I. INTRODUCTION

One of the primary aims of the LHC’s physics mission is to search for beyond the standard model (BSM) physics. A key motivation for BSM physics arises from the cosmological observations of dark matter (DM). Thus far, multiple observations have inferred the existence of DM through its gravitational interactions with baryonic matter (see Ref. [1] for a recent review); however, to date, no observation of nongravitational interactions of DM has been conclusively established. The search for nongravitational interactions of DM is hence an ongoing and exciting area of active research.

At the LHC the putative DM particle, or any similarly weakly-interacting BSM state, will not be directly observed by the LHC detectors. Instead the particle may be pair-produced in association with jets, that are observed in copious amounts at the LHC. If the DM particle couples to the SM through a heavy mediator then the typical transverse energy of the DM pair will be large, with the jets accounting for the corresponding recoil in the transverse plane. This would allow the presence of the DM to be inferred from an excess of events with large missing transverse energy (MET). As a result the MET + jets channel is one of the most exciting and rich channels in which to search for BSM effects (for a recent overview see Ref. [2]).

Unfortunately, the standard model (SM) itself also provides a substantial source of events with large MET. The largest source of such events is through the production of a Z boson in association with jets, with the subsequent decay $Z \to \nu\bar{\nu}$. Since the invisible decay forbids the reconstruction of the invariant mass of the parent Z boson, this background cannot be easily suppressed by an explicit mass-window cut. This presents a significant challenge for MET + jet searches. Thankfully the visible decays of the Z provide a window through which to study this irreducible background [3,4]. Decays of the Z boson to light charged leptons, $Z \to e^+e^-$ and $Z \to \mu^+\mu^-$, are clean experimental signatures with excellent resolution. By studying the impact of artificially not taking into account the visible leptons, the effect of the transition to MET-based observables can be easily quantified. However, a secondary issue arises when using the charged leptons as a tool to measure the neutrino background. Since the invisible decay forbids the $Z \to \nu\bar{\nu}$ channel, the low statistics of the $Z \to \nu\bar{\nu}$ background limits its utility for estimating the $Z \to \nu\bar{\nu}$ background.

In the region of high $p_T^\ell$, one must, therefore, find an alternate strategy for calibrating the MET + jets background. One possibility is to make use of the sample of $\gamma + j$ events. The photon and Z boson are similar enough that a comparison of their production mechanisms is useful and, since one does not have to pay the price of a branching ratio for the photon, there is a factor of $\sim 100$ more events at high $p_T$. One can, therefore, measure the ratio of $\ell^+\ell^- + j$ and $\gamma + j$ events at low $p_T$ and extrapolate into the high $p_T^\ell$ region. A good agreement between theory and data for this ratio is crucial; only once it has been demonstrated at lower values of $p_T^\ell$ can the method be
applied with confidence in the region of limited data at higher values of $p_T^\gamma$.

Theoretical predictions for the $Z+j$ and $\gamma+j$ processes have been available at NLO for a long time [5,6]. From these calculations the theoretical uncertainty associated with a truncation of the perturbative expansion at this order may be estimated from the sensitivity of the predictions to the choice of factorization, renormalization and (in the case of $\gamma+j$) fragmentation scales. These are typically in the range of 10%–20%, which has been sufficient for testing the SM in these channels in the past. However, as the LHC accumulates more data of this nature [7–10], the experimental uncertainties are approaching the level of a few percent and will only decrease further. In order to achieve a similar level of theoretical precision it is necessary to include additional perturbative corrections. For the case of $Z+j$ production, NNLO QCD corrections have been extensively studied by now [11–14]. At this level of accuracy it is also necessary to include the effect of NLO electroweak corrections, which are also known for this process [15–18]. For $\gamma+j$ production, the closely-related direct photon process has recently been computed at NNLO in QCD [19] and the NLO EW corrections are known as well [20].

In this paper we will provide NNLO predictions for $\gamma+j$ production, thus bringing the theoretical prediction to the same level as for the $Z+j$ process. To do so we will make use of the direct photon calculation of Ref. [19], that has already been implemented in the Monte Carlo code MCFM, and explicitly demand the presence of a jet. With this calculation in hand we will be able to address the main aim of this paper, which is predicting the $\mathcal{L}^+\mathcal{L}^-+\text{jet}/\gamma+\text{jet}$ ratio with an accounting of NNLO QCD and leading EW effects.\footnote{Our work, thus, expands upon a recent comparison of combined NLO QCD + EW effects and CMS data that was performed as part of a Les Houches study [21].} To do so we will also make use of the MCFW implementation of the NNLO corrections to $Z+j$ production [12].

II. CALCULATION

A. IR regularization

NNLO calculations require regularization of infrared singularities that are present in phase spaces with different numbers of final state partons. In our calculations we use the $N$-jettiness slicing approach that was outlined in Refs. [22,23], based on earlier similar applications to top-quark decay at NNLO [24]. This method follows a divide-and-conquer approach to regulating the singularities in the calculation. A cut on the $N$-jettiness variable $\tau_N$ [25] is introduced, where $N$ is the number of jets in the Born phase space. For the case at hand $N = 1$. Therefore, we introduce the following variable

$$\tau_1 = \sum_{k=1}^{M} \min_{i \neq a,b} \left\{ \frac{2 d_i \cdot p_k}{Q_i} \right\}.$$ (1)

Where $\{p_k\}$ defines the momenta of the parton-level configuration, and $\{q_i\}$ represents the set of momenta that is obtained after application of a jet-clustering algorithm. The scale $Q_i$ is a measure of the jet or beam hardness, which we take as $Q_i = 2 E_i$. The labels $a$ and $b$ refer to the two beam partons. Note that if $\tau_1 = 0$ then the clustered momenta map directly onto the Born phase space (i.e. a one-jet configuration). Nonzero values of $\tau_1$, therefore, correspond to configurations with a greater number of partons than the Born phase space. We introduce a cut choice $\tau_1^\text{cut}$ such that when $\tau_1 > \tau_1^\text{cut}$ the components of the calculation contain at most single-unsuspected infrared singularities. It, therefore, corresponds to a NLO calculation with an additional parton, albeit one which must be integrated with an extremely loose jet requirement. The double-unsuspected singularities reside in the region $\tau_1 < \tau_1^\text{cut}$, where the application of SCET [26–30] allows us to write the cross section as follows,

$$\sigma(\tau_1 < \tau_1^\text{cut}) = \int \mathcal{H} \otimes B \otimes B \otimes S \otimes J + \mathcal{O}(\tau_1^\text{cut}).$$ (2)

That is, the cross section factorizes into a convolution of process-independent beam ($B$) and jet ($J$) functions, a soft function $S$ (which depends on the number of colored scatters) and a (finite) process-specific hard function $\mathcal{H}$. Expansions accurate to $\mathcal{O}(a_s^2)$, that are relevant for our calculation, can be found in Refs. [31–35] for the beam, jet and soft functions, respectively. The hard functions for the processes we consider in this paper are written in terms of the two-loop virtual matrix elements that have been calculated in Ref. [36] and Refs. [37,38] for the $\gamma+j$ and $Z+j$ cases, respectively. Their implementation has been discussed in Ref. [12] for $Z+j$ production and in Ref. [19] for direct photon production, which shares the same hard function as the photon + jet case we consider here. A key consideration within the $N$-jettiness slicing approach is the choice of $\tau_1^\text{cut}$ used for the calculation. As indicated in Eq. (2), the below-cut factorization theorem receives power corrections that vanish in the limit $\tau_1^\text{cut} \rightarrow 0$, but they can have a sizable impact on the cross section for nonzero values. Therefore, it is crucial that $\tau_1^\text{cut}$ be taken as small as possible, to minimize the impact of these corrections.\footnote{For recent work on reducing the dependence on power corrections, see Refs. [39,40].} A general discussion of the process-specific parts of the direct photon and $Z+j$ calculations in MCFM was presented in Refs [12,19]. For brevity, we will not reproduce that discussion here, but refer the interested reader to the original works for further details. Instead, in this paper we will focus on the validation of both calculations for the specific phase space selection criteria employed by the CMS analysis that we will follow.
B. Parameter choices

The usual MCFM EW parameter choice is the $G_F$ scheme, in which the values of $M_W$, $M_Z$ and $G_F$ (the Fermi constant) are taken as inputs. In this scheme the electromagnetic coupling is then defined, at leading order, as

$$\alpha_{e.m.} = \frac{G_F M_W^2}{\pi} \left( 1 - \frac{M_W^2}{M_Z^2} \right)$$

This is an appropriate choice for the description of $Z + j$ production, a process that is clearly sensitive to the electromagnetic term. With the following choice of parameters,

$$M_Z = 91.1876 \text{ GeV}, \quad \Gamma_Z = 2.4952 \text{ GeV},$$
$$M_W = 80.385 \text{ GeV}, \quad \sin^2 \theta_w = 0.222897,$$

the relation in Eq. (3) leads to a value of the electromagnetic coupling,

$$\alpha|_{Z+j} = \frac{\alpha}{132.232}.$$

For the calculation of $\gamma + j$ production, a process that involves a real photon in the final state, it is not clear that such a choice is the correct one. For on-shell photons a natural alternative is provided by the $a(0)$ scheme in which the coupling is given by the fine-structure constant. Since we will later include the effects of NLO electroweak contributions for the $\gamma + j$ process that have been computed in this scheme [20], we choose

$$\alpha|_{\gamma+j} = \alpha(0) = \frac{\alpha}{137.036}.$$

We will choose both renormalization ($\mu_R$) and factorization ($\mu_F$) scales equal to $H_T$, which is defined event-by-event to be the scalar sum of the transverse momenta of all partons, leptons and photons present. When studying the theoretical uncertainty associated with this choice of scale, we consider a six-point variation corresponding to,

$$\mu_R = r H_T, \quad \mu_F = f H_T,$$

with $r, f \in \left( \frac{1}{2}, 1, 2 \right)$ and $rf \neq 1$. We use the NNLO CT14 set of parton distribution functions [42] for all predictions, where $\alpha_s(M_Z) = 0.118$ is taken from the PDF set. Studies of the associated PDF uncertainty are performed using the additional 56 eigenvector sets provided through LHAPDF6 [43] and are quoted at the 68% confidence level.

C. Event selection

Our phase space selection criteria are based on those used in a recent CMS analysis of 8 TeV data [44]. For the photon plus jets sample we require that the photon satisfies the following cuts:

$$p_T^\gamma > 100 \text{ GeV}, \quad |\eta| < 1.4.$$  

Both experimentally and theoretically, photons require isolation from hadronic activity. On the experimental side, this reduces unwanted backgrounds from pion decays and photons that arise from fragmentation processes. Theoretically, the calculation is simplified if smooth cone isolation [45] is employed. In that case, one requires that the photon satisfies

$$\sum p_T^{\text{had}}(R) < e_{\gamma} p_T^\gamma \left( \frac{1 - \cos R}{1 - \cos R_0} \right)^n \forall R < R_0.$$  

This requirement constrains the sum of the hadronic energy inside a cone of radius $R$, for all separations $R$ that are smaller than a chosen cone size, $R_0$. Cones are defined in terms of the $R$ variable,

$$R = \sqrt{\Delta\eta^2 + \Delta\phi^2},$$

where $\eta$ and $\phi$ are the pseudorapidity and azimuthal angle of the particle, respectively. Note that arbitrarily soft radiation will always pass the condition, but collinear ($R \to 0$) radiation is forbidden. This removes the collinear splittings associated with fragmentation functions, at the cost of no longer reproducing the form of isolation applied in experimental analyses. In this paper we set $e_{\gamma} = 0.025$, $R_0 = 0.4$ and $n = 2$ in Eq. (9). This matches the parameters employed in a similar analysis by the BlackHat collaboration [3]. At NLO we can explicitly quantify the difference between following this procedure and performing a calculation that includes the effects of fragmentation. We shall see later that this difference is small, around a percent in the photon $p_T$ spectrum.

In addition to the photon requirements described above, we require the presence of at least one jet in the event. Jets are defined using the anti-$k_T$ [47] algorithm with $R = 0.5$ and satisfy

$$p_T^j > 30 \text{ GeV}, \quad |\eta_j| < 2.4.$$  

Additionally, we require that photons and jets are separated by $R_{\gamma j} > 0.5$.

For the $Z + j$ sample we require that the charged leptons are in the following fiducial volume,

---

[3] See for instance the discussion in Sec. IV.E.2 of Ref. [41].
processes, so that the resulting uncertainty on $\Delta \tau$ for the two processes we see that, as expected, the dependence on cuts have been chosen to emphasize the similarity between for both of the processes considered in this paper. Since the traction method and only calculated using a traditional Catani-Seymour dipole sub-

This is perfectly acceptable for phenomenological purposes power corrections and Monte Carlo statistics is below 1%. We require that the lepton pair resides in an invariant mass window close to the Z mass, $71 < m_{\ell\ell} < 111$ GeV, and that the leptons are isolated from jets, $R_{\ell\ell} > 0.5$. We also require that $p_T^\ell > 100$ GeV and $|y_{\ell\ell}| < 1.4$ to mimic the photon selection as closely as possible.

D. $\tau_1^{cut}$ dependence

Before providing NNLO predictions for $\gamma + j$ (and $Z + j$) production we first validate our calculation for the phase space cuts described in the previous section. Since the $N$-jettiness slicing method is sensitive to power corrections it is crucial to validate the calculation for a new phase space selection. At NNLO, the cross section can be written as

$$\sigma_{NNLO} = \sigma_{NLO} + \Delta \sigma_{NNLO},$$

where $\sigma_{NLO}$ is the NLO cross section and $\Delta \sigma_{NNLO}$ represents the correction that arises at NNLO. In MCFM, $\sigma_{NLO}$ is calculated using a traditional Catani-Seymour dipole subtraction method [48] and only $\Delta \sigma_{NNLO}$ is computed using $N$-jettiness slicing. Therefore, only $\Delta \sigma_{NNLO}$ has a dependence on $\tau_1^{cut}$, a sensitivity that is indicated in Fig. 1. This figure shows the ratio $\Delta \sigma_{NNLO}(\tau_1^{cut})/\Delta \sigma_{NNLO}(\tau_1^{cut} = 0.06$ GeV), for both of the processes considered in this paper. Since the cuts have been chosen to emphasize the similarity between the two processes we see that, as expected, the dependence on $\tau_1^{cut}$ is also comparable. Below $\tau_1^{cut} = 0.1$ GeV the predictions are insensitive to the choice of $\tau_1^{cut}$ within Monte Carlo uncertainties which, in this region, are around 5%. We will see that $\Delta \sigma_{NNLO}/\sigma_{NNLO}$ is approximately 5%--10% for both processes, so that the resulting uncertainty on $\sigma_{NNLO}$ due to power corrections and Monte Carlo statistics is below 1%. This is perfectly acceptable for phenomenological purposes.

$^5$We note that the MC uncertainties are all rescaled by the central value at $\tau_1^{cut} = 0.06$ GeV such that there is no reduction in uncertainties due to the fact that the plotted quantity is a ratio.

and, given the results in Fig. 1, we choose $\tau_1^{cut} = 0.08$ GeV to compute the remainder of the results in this paper.

E. Electroweak corrections

Since data sets at the LHC now permit the study of $\gamma +$ jet and $Z +$ jet events in which the photon or Z boson carries a transverse momentum approaching 1 TeV, it is imperative to also account for the effect of electroweak corrections in theoretical predictions for these processes. Although these are generically expected to be rather small, at such high transverse momenta they give rise to Sudakov-enhanced corrections of the order of 10% or more. These primarily arise from the contribution of loop diagrams in which a virtual W or Z boson is exchanged, resulting in leading logarithms of the form $\log^2(M_V/p_T)$, whose effects on these processes have been known for some time [15,16,20]. More recently these effects have also been computed in the framework of SCET [49,50]. We note that the effect of photon radiation from leptons is not captured in any of these calculations.

In this paper we shall make use of the results of Refs. [16,20] in order to account for electroweak effects. The impact of the electroweak corrections can be captured by expressing their effect on the cross section ($\sigma_{EW}$) as a fraction of the leading-order result,

$$\Delta_{EW} = \frac{\sigma_{EW}}{\sigma_{LO}}.$$ (14)

We will treat the EW corrections as factorizing fully with respect to the QCD ones and simply multiply our NNLO QCD predictions by $1 + \Delta_{EW}$. The calculation of $\sigma_{EW}$ is performed using expressions that are valid in the high-energy limit and are NNLL accurate; these are specified in Sec. III. E of Ref. [16] and Sec. III. C of Ref. [20]. We have checked that this calculation agrees well with the results presented in Refs. [49,50], up to numerical differences that are negligible for $\gamma + j$ production and are less than 1% for $Z + j$.

III. DIFFERENTIAL PREDICTIONS FOR $\gamma + j$

Before arriving at the primary interest of this paper, an analysis of the $Z + j/\gamma + j$ ratio at NNLO, we first consider the $\gamma + j$ process on its own. As discussed in the introduction, the $Z + j$ process has been extensively studied at NNLO, including detailed phenomenological analyses [11–14]. No such studies exist for the $\gamma + j$ process at this order and a careful analysis is a prerequisite to studying the ratio in detail. Therefore, in this section, we compare the predictions of MCFM for $\gamma + j$ production to CMS data collected at 8 TeV. The fundamental quantity of interest is the photon transverse momentum spectrum, which we present in Fig. 2. The correction from NLO to NNLO is around 10% and the NNLO prediction lies just at the very top of the scale variation band obtained at NLO.
The NNLO/NLO $K$-factor is reasonably flat, with a slight increase at higher $p_T$. The scale variation at NNLO is significantly reduced compared to that obtained at NLO, with a typical variation of 2%–3% compared to 8%–10% at NLO. Although the NNLO prediction lies closer to the CMS data than the NLO one, both predictions are consistently lower than the experimental measurements.

We now include the effect of electroweak corrections as discussed above, by rescaling the complete NNLO result by the change observed in the LO prediction when including one-loop electroweak effects. We denote this combination by the shorthand NNLO\((1 + \Delta_{\text{EW}})\). Figure 3 shows the ratio of data and the NNLO prediction to the pure NNLO prediction for the photon $p_T$ spectrum. The upper panel shows the raw ratio, while the lower panel normalizes all predictions to their central value in the $p_T \in [100, 111]$ GeV bin, allowing us to compare the shape of the predictions. We note that this procedure results in an overestimate of the errors on the CMS data, since a normalized distribution should not be sensitive to the overall luminosity. However, for the purposes of this comparison this overestimate can be tolerated. However, a full analysis of the shape of the distribution measured by the LHC collaborations and a comparison to its theory counterparts is clearly very desirable. The upper panel shows that, by including the EW corrections, the apparent agreement between theory and data gets worse. However, the lower panel shows that the shape of the data and theory predictions are actually in very good agreement.

We have so far only considered the theoretical uncertainty originating from the choice of scale and demonstrated that it is significantly reduced at NNLO, by a factor of two. However there are other origins of theoretical uncertainty, beyond scale variation, that affect our prediction. We will now consider two other sources of theoretical uncertainty: the choice of PDFs and the form of the photon isolation. These may primarily affect the normalization of the theoretical prediction, or may induce changes in the shape of the distributions. For PDF uncertainties we will consider the 68% confidence level uncertainties provided by LHAPDF6 [43] where, for efficiency, these uncertainties are computed from the NLO prediction (using NNLO CT14 PDFs). We have checked that the difference in PDF uncertainty obtained from LO and NLO calculations using this set is very small, so that we are confident that this provides a reliable estimate of the PDF uncertainty for our NNLO prediction. In order to quantify the effect of the difference between our isolation prescription and that of the experimental analysis, we repeat our NLO calculation using the parton-level version of the experimental isolation procedure:

$$E_T^{\text{had}} < 5 \text{ GeV} \quad \forall \ R < R_0.$$  \hspace{1cm} (15)

Here, as in the smooth cone version, $R_0 = 0.4$ and our calculation employs the GdRG fragmentation functions [51]. Since the difference between the methods of isolating the photon could be affected differently at NNLO we
should provide a conservative estimate of this effect.

We, therefore, estimate the isolation uncertainty by taking the difference between the two isolation procedures, multiplying by an additional factor of two, and allowing excursions from our central result by this amount on either side.

Our results for the uncertainty in the theoretical prediction for the photon \( p_T \) spectrum are presented in Fig. 4. The uncertainties are normalized to the central value of the combined NNLO QCD + NLO EW prediction. We observe that at NNLO the scale variation and PDF uncertainty are roughly equal and correspond to a few percent uncertainty. The PDF uncertainty grows more rapidly as a function of photon transverse momentum and is largest in the highest bins (~5%). The uncertainty stemming from the isolation procedure is at the level of 2% for lower values of \( p_T \) but is significantly smaller in the tail. This is in line with previous studies of the difference between smooth cone isolation and the forms used in experimental analyses [19,52]. The total uncertainty from scales, PDFs and isolation, obtained by adding the individual uncertainties linearly, ranges from around 4% at low \( p_T \) to 9% in the highest bins. Clearly the large PDF uncertainty can be reduced in the future [53,54], by taking advantage of calculations such as this one in tandem with the even bigger \( \gamma + j \) data sets being accumulated at the LHC.

The tension that remains between the data and our theoretical prediction, displayed in the lower panel of Fig. 4, could have a number of sources. Although we have endeavored to be thorough, the accounting of theoretical uncertainty could yet be deficient. On the experimental side, the normalization of the data could be changed by a host of factors, including a reduction in the overall luminosity, a change in the photon efficiency, or an issue with background subtraction.\(^6\)

A further interesting observable to consider is the ratio of inclusive \( \gamma + 2j \) to \( \gamma + j \) production as a function of the photon transverse momentum. Fixed-order calculations of this ratio can be broken down into contributions proportional to the relevant powers of the strong coupling as follows,

\[
R_{2/1}(p_T^\gamma) = \frac{\alpha_s^2 \sum_{i=0}^{n_2} \alpha_i^2 d_{1+j_2}^{(k)} / dp_T^\gamma}{\alpha_s \sum_{k=0}^{n_1} \alpha_i^2 d_{1+j_1}^{(k)} / dp_T^\gamma}.
\]

(16)

In this expression we have made clear that contributions to the denominator start with one power of \( \alpha_s \) and those to the numerator with two. An inclusive calculation of \( \gamma + j \) production, such as the one we are considering in this paper, naturally contains terms in the numerator up to \( n_2 = n_1 - 1 \). Our NNLO calculation corresponds to \( n_1 = 2 \) while the equivalent result from our NLO calculation is given by \( n_1 = 1 \). We call these predictions \( R_{2/1}^{\text{NNLO}} \) and \( R_{2/1}^{\text{NLO}} \), respectively, and compare them to the CMS measurement of the same ratio in Fig. 5. \( R_{2/1}^{\text{NNLO}}(p_T^\gamma) \) does a poor job of describing the data because it is a LO calculation for this observable and thus bears all the hallmarks of such a calculation. This is not only reflected by a general underestimation of the data, but also by the rather large scale dependence. The corrections to this ratio when moving to \( R_{2/1}^{\text{NNLO}}(p_T^\gamma) \) are large, around 30%.

The agreement with data is significantly improved and the scale uncertainty is reduced by a factor of two.

However, from Eq. (16), it is clear that neither of the predictions presented so far corresponds to a strict expansion of the ratio to a given power of the strong coupling, due to the fact that the denominator contains an additional term of one order higher than the numerator. Instead, we can define alternative predictions, corresponding to \( n_2 = n_1 \), with \( R_{2/1}^{\text{NLO}^*} \) given by \( n_1 = n_2 = 1 \). Note that the alternative definition \( R_{2/1}^{\text{NLO}^*} \) can be obtained by simply taking the ratio of two NLO calculations of \( \gamma + 2j \) and \( \gamma + j \) production. This is the procedure already followed by CMS [44] using the results of Ref. [3]. Since the NNLO corrections to \( \gamma + 2j \) production are unknown, and likely to remain so for some time, it is useful to estimate the potential impact that they could have on the theoretical prediction for \( R_{2/1} \). We do so by postulating NNLO corrections given by,

---

\(^6\)We note that the CMS paper [44] indicates a flat 2.6% luminosity uncertainty over the whole \( p_T^\gamma \) range, which is far below the level of disagreement indicated here.
the prediction for the quantity, the data for
FIG. 6. The quantity $R^{\text{NLO}}_{2/1}(p_T^\gamma)$, a range of estimates for $R^{\text{NNLO}}_{2/1}(p_T^\gamma)$ computed as discussed in the text, and the CMS measurements [44]. All quantities are normalized to the theoretical prediction $R^{\text{NLO}}_{2/1}(p_T^\gamma)$.

FIG. 5. The quantities $R^{\text{NLO}}_{2/1}(p_T^\gamma)$ and $R^{\text{NNLO}}_{2/1}(p_T^\gamma)$ compared to CMS data from Ref. [44]. The bands indicate the scale uncertainty on the theoretical predictions.

\begin{equation}
\frac{\sigma^{(2,\text{approx})}_{T+2j}}{dp_T^\gamma} = \pm \frac{\left[\sigma^{(1)}_{T+2j}/dp_T^\gamma\right]^2}{\sigma^{(0)}_{T+2j}/dp_T^\gamma},
\end{equation}

where, as indicated, the corrections can be of either sign. In this way, the NNLO corrections are of the same size relative to NLO as the NLO ones are to LO. A comparison of the results for $R^{\text{NLO}}_{2/1}$ and the two bounding estimates of $R^{\text{NNLO}}_{2/1}$, with both our calculation of $R^{\text{NNLO}}_{2/1}$ and the CMS data, is shown in Fig. 6. We see that, as observed already in Ref. [44], the prediction $R^{\text{NNLO}}_{2/1}$ is in good agreement with the data for $p_T^\gamma < 200$ GeV but overshoots it by around 15% at high $p_T^\gamma$. The range of the estimate $R^{\text{NNLO}}_{2/1}$ brackets both the theory predictions $R^{\text{NLO}}_{2/1}$ and $R^{\text{NNLO}}_{2/1}$, as well as the data, and is of a similar size as the scale uncertainty on $R^{\text{NNLO}}_{2/1}$ shown in Fig. 5. In addition, the data suggest that NNLO corrections to $\gamma + 2j$ production might be expected to be small at high $p_T^\gamma$. In summary, $R^{\text{NNLO}}_{2/1}$ provides a fairly good description of the data, and we believe that the associated scale uncertainty provides a plausible envelope for the results of a complete NNLO calculation of this ratio ($R^{\text{NNLO}}_{2/1}$).

IV. THE $Z/\gamma$ RATIO AT NNLO

We are now able to address the principal aim of this paper, which is improving the theoretical prediction for the ratio of $Z + j$ and $\gamma + j$ production. We consider the case where the $Z$-boson decays to leptons and the two processes are studied in a similar kinematic regime by application of the cuts described in Sec. II C. Specifically, we consider predictions for the quantity,

\begin{equation}
R_{Z/\gamma}^O(p_T) = \frac{d\sigma^O_{\ell^-\ell^+ + j + X}}{dp_T^\gamma} \sqrt{\frac{O_{Z/\gamma}}{O_{Z/\gamma}}},
\end{equation}

where $p_T$ represents the transverse momentum of the $Z$ boson or photon. A simple expectation for the behaviour of this ratio can be obtained by considering only the effect of the different $Z$ and photon couplings, together with the effect of the PDFs, in the LO cross section. This neglects the effect of the $Z$-boson mass, which should be irrelevant at large $p_T^\gamma$, as well as the impact of higher-order corrections. The ratio is then estimated to be [4],

\begin{equation}
R_{Z/\gamma} = \left( R_u + R_d - R_u \right)[Br(Z \to \ell^-\ell^+) \times A],
\end{equation}

where $R_q$ is the relevant ratio of quark-boson couplings squared,

\begin{equation}
R_q = \frac{\langle u \rangle^2 + \langle d \rangle^2}{4m_2^2\sin^2\theta_c\cos^2\theta_wQ_q^2},
\end{equation}

and $\langle u \rangle$ ($\langle d \rangle$) is the typical up (down) quark PDF at the value of $x$ probed by a given $p_T^\gamma$, i.e. $\langle x \rangle = 2p_T^\gamma/\sqrt{\mu}$. The branching ratio and acceptance factor ($A$) account for the $Z$-boson decay and cuts on the leptons. At high transverse momentum, $p_T^\gamma \gg M_Z$, $x \rightarrow 1$ and $\langle u \rangle/\langle d \rangle \rightarrow \infty$, so that $R_{Z/\gamma}$ should slowly approach an asymptotic value from above [3,4]. This argument thus predicts a plateau at high transverse momentum, which we will observe shortly in our full prediction. We stress that in our calculation this ratio is not computed for on-shell $Z$ bosons but includes the decay into leptons, off-shell effects and the (small) contribution from virtual photon exchange. Nevertheless, we will refer to this quantity as $R_{Z/\gamma}$, or the $Z/\gamma$ ratio, as a matter of convenience.
When computing this ratio a subtlety arises when trying to provide an uncertainty estimate based on scale variation. If the variation is correlated, i.e. one computes the scale uncertainty using the same scale in both the numerator and denominator of Eq. (18), then one obtains essentially no uncertainty on \( R_{Z/\gamma}^\gamma(p_T) \), even at NLO. We, therefore, discard this choice as a useful measure of the theoretical uncertainty. The alternative that we use instead is to consider variations of the scale in the numerator and denominator separately,

\[
\frac{d\sigma_F^{O,(r,f)}_{r+j+X}/dp_T}{d\sigma_F^{O,(r,f)}_{r+j+X}/dp_T} \quad \text{and} \quad \frac{d\sigma_F^{O,(r,f)}_{r+j+X}/dp_T}{d\sigma_F^{O,(r,f)}_{r+j+X}/dp_T},
\]

where \( \{r,f\} \) represents the six-point scale variation indicated in Eq. (7). The uncertainty is then defined by the extremal values of either of these two ratios. In practice, since the scale-dependence of the two processes is so similar, this procedure is almost identical to defining the uncertainty in terms of the variation of either quantity in Eq. (21) alone. In contrast to the correlated variation, this approach results in scale uncertainties that, order-by-order, overlap both the data and the central result of the next-higher order. Moreover, with this procedure, at NNLO the resulting uncertainty band is of a size typical of a NNLO prediction and still smaller than the experimental uncertainties.

Our results for the ratio for the pure QCD NLO and NNLO calculation are shown in Fig. 7. The most significant effect of the NNLO calculation is to decrease the ratio, particularly at lower values of \( p_T \). We have already seen, in Fig. 3, that the shape of the \( p_T \) spectrum is significantly improved by the inclusion of electroweak effects. We, therefore, extend our prediction for this ratio by taking such corrections into account, rescaling the individual \( p_T \) spectra by \( (1 + \Delta_{EW}^V) \) as discussed previously. Since the electroweak corrections do not affect the \( Z + j \) and \( \gamma + j \) processes in the same way [20], this leads to a modification of the prediction for this ratio that is shown in Fig. 8. Although the effects are minor in the low-\( p_T \) region, as expected, they become more important in the highest bins. There they decrease the ratio by as much as 7% and thereby improve the agreement with the CMS data.

We now consider a full analysis of the theoretical uncertainties associated with the calculation of \( R_{Z/\gamma}^{\text{NNLO}+\text{EW}} \), using the same procedure as discussed earlier for the photon \( p_T \) spectrum. Our results are presented in Fig. 9 where, as before, the uncertainties are normalized to the central value of the combined NNLO QCD + EW prediction. We see that the PDF uncertainties essentially cancel, as one might expect from the nature of the ratio. The dominant uncertainty results from scale variation, especially at high \( p_T^\gamma \). The total uncertainty is only around 4% in the lowest bins and is slightly higher, approximately 6%, at high \( p_T^\gamma \).

As discussed earlier, the asymptotic behavior of our prediction for \( R_{Z/\gamma} \) is particularly interesting. In order to quantify this we follow the CMS analysis [44] and define a ratio in which the high-\( p_T \) bins are integrated over...
The experimental measurement of this quantity by CMS is

$$R_{\text{CMS}}^{\text{dilep}} = 0.0322 \pm 0.0008 \text{(stat)} \pm 0.0020 \text{(syst)}.$$ 

Our best theoretical prediction is provided by the NNLO + EW prediction shown in Fig. 8, with accompanying uncertainties illustrated in Fig. 9. We find

$$R_{\text{dilep}}^{\text{NNLO} + \text{EW}}(8 \text{ TeV}) = 0.0359_{-0.0013}^{+0.0012} \text{(scale)}_{-0.0004}^{+0.0004} \text{(PDF)}_{-0.0006}^{+0.0006} \text{(iso)}.$$ 

Given the level of the residual uncertainties, this result is in reasonable agreement with the measured value, $R_{\text{CMS}}^{\text{dilep}}$.

The CMS collaboration has not yet performed a similar analysis of $\gamma + j$ production at 13 TeV. Since such an undertaking will likely involve a change in the cuts that are applied, or at least in the binning of the final data, for now we refrain from performing a detailed study of individual distributions at this energy. However it is especially important to predict the ratio $R_{Z/\gamma}(p_T)$ and, in particular, its value in the high-$p_T$ tail. For this reason we repeat our above analysis at 13 TeV, with no cuts or input parameters altered apart from the LHC operating energy.

Our prediction for $R_{Z/\gamma}(p_T)$ at 13 TeV is shown in Fig. 10, where we compare predictions at NLO, NNLO and when combining NNLO QCD and EW effects. As before (cf. Figs. 7 and 8), we see that the ratio is very similar in all cases, but that the NNLO prediction has a substantially smaller uncertainty and the inclusion of EW effects lowers the ratio at high $p_T$. At 13 TeV, we are further from the large-$x$ region, for the same range of $p_T$, so that the $\langle u \rangle / \langle d \rangle$ ratio in Eq. (19) is smaller. We thus expect that the value of $R_{\text{dilep}}$ is higher at 13 TeV than at 8 TeV, a supposition that is borne out by our explicit calculations. We find, for the asymptotic ratio defined in Eq. (22),

$$R_{\text{dilep}}^{\text{NNLO} + \text{EW}}(13 \text{ TeV}) = 0.0387_{-0.0011}^{+0.0013} \text{(scale)}_{-0.0004}^{+0.0004} \text{(PDF)}_{-0.0006}^{+0.0006} \text{(iso)}.$$ 

Given the level of the residual uncertainties, this result is in reasonable agreement with the measured value, $R_{\text{CMS}}^{\text{dilep}}$.

The CMS collaboration has not yet performed a similar analysis of $\gamma + j$ production at 13 TeV. Since such an undertaking will likely involve a change in the cuts that are applied, or at least in the binning of the final data, for now we refrain from performing a detailed study of individual distributions at this energy. However it is especially important to predict the ratio $R_{Z/\gamma}(p_T)$ and, in particular, its value in the high-$p_T$ tail. For this reason we repeat our above analysis at 13 TeV, with no cuts or input parameters altered apart from the LHC operating energy.

Our prediction for $R_{Z/\gamma}(p_T)$ at 13 TeV is shown in Fig. 10, where we compare predictions at NLO, NNLO and when combining NNLO QCD and EW effects. As before (cf. Figs. 7 and 8), we see that the ratio is very similar in all cases, but that the NNLO prediction has a substantially smaller uncertainty and the inclusion of EW effects lowers the ratio at high $p_T$. At 13 TeV, we are further from the large-$x$ region, for the same range of $p_T$, so that the $\langle u \rangle / \langle d \rangle$ ratio in Eq. (19) is smaller. We thus expect that the value of $R_{\text{dilep}}$ is higher at 13 TeV than at 8 TeV, a supposition that is borne out by our explicit calculations. We find, for the asymptotic ratio defined in Eq. (22),

$$R_{\text{dilep}}^{\text{NNLO} + \text{EW}}(13 \text{ TeV}) = 0.0387_{-0.0011}^{+0.0013} \text{(scale)}_{-0.0004}^{+0.0004} \text{(PDF)}_{-0.0006}^{+0.0006} \text{(iso)}.$$ 

Given the level of the residual uncertainties, this result is in reasonable agreement with the measured value, $R_{\text{CMS}}^{\text{dilep}}$.
We conclude this section with a summary of the theoretical predictions for $R_{\text{dilep}}$, computed at various orders of perturbation theory, shown in Fig. 11. The improvement in the precision of the theoretical prediction when going from NLO to NNLO QCD is clear. It also emphasizes that, after the inclusion of electroweak effects, there is better agreement between the best theoretical prediction and the measurement of CMS [44]. However, some tension still remains in the overall normalization. This could perhaps be relieved somewhat by the use of an alternative electroweak scheme in which the coupling in the $\gamma + j$ process is evaluated at a higher scale rather than using $\alpha(0)$. This would require proper inclusion of the appropriate counterterms in the one-loop EW calculation and such a study is beyond the scope of this work.

V. CONCLUSIONS

In this paper, we have presented differential predictions for $\gamma + j$ production at NNLO and compared our predictions to data taken by the CMS experiment at 8 TeV. We have seen that NNLO predictions provide a very good description of the shape of the CMS data, with the inclusion of EW effects improving the agreement further still. For the $p_T^\gamma$ distribution, there is an apparent disagreement between the normalization of the theoretical prediction and the observed data, but again the shapes of the theory and data are very similar. We have used our results to compute several other quantities, notably the ratio of $Z + j$ and $\gamma + j$ production as a function of the boson transverse momentum, which is useful for estimating backgrounds to BSM searches. The agreement between the theoretical prediction and data for this ratio is satisfactory. Finally, we have made additional predictions at NNLO accuracy for future studies of the $Z + j/\gamma + j$ ratio at 13 TeV.

APPENDIX: NUMERICAL RESULTS

Our numerical results for the $Z + j$ to $\gamma + j$ ratio studied in this paper, $R_{Z/j}$, are presented in Table I (8 TeV) and Table II (13 TeV). For each bin of $p_T^\gamma$, we show the value of the ratio computed to NLO and NNLO accuracy, the associated uncertainty due to scale variation as described in the text, and the EW rescaling factor.

Table I. The values of $R_{Z/j}^{\text{NLO}}$ and $R_{Z/j}^{\text{NNLO}}$ at 8 TeV (rescaled by a factor of 100), together with the additional correction that corresponds to including EW effects in both processes. Quoted ranges correspond to the variation in the central scale by the six-point method described in the text.
