Triazatruxene: A Rigid Central Donor Unit for a D–A₃ Thermally Activated Delayed Fluorescence Material Exhibiting Sub-Microsecond Reverse Intersystem Crossing and Unity Quantum Yield via Multiple Singlet–Triplet State Pairs

Paloma L. dos Santos, Jonathan S. Ward, Daniel G. Congrave, Andrei S. Batsanov, Julien Eng, Jessica E. Stacey, Thomas J. Penfold, Andrew P. Monkman,* and Martin R. Bryce*

By inverting the common structural motif of thermally activated delayed fluorescence materials to a rigid donor core and multiple peripheral acceptors, reverse intersystem crossing (rISC) rates are demonstrated in an organic material that enables utilization of triplet excited states at faster rates than Ir-based phosphorescent materials. A combination of the inverted structure and multiple donor–acceptor interactions yields up to 30 vibronically coupled singlet and triplet states within 0.2 eV that are involved in rISC. This gives a significant enhancement to the rISC rate, leading to delayed fluorescence decay times as low as 103.9 ns. This new material also has an emission quantum yield =1 and a very small singlet–triplet gap. This work shows that it is possible to achieve both high photoluminescence quantum yield and fast rISC in the same molecule. Green organic light-emitting diode devices with external quantum efficiency >30% are demonstrated at 76 cd m⁻².

1. Introduction

Organic light-emitting diodes (OLEDs) have become a central part of materials research, with the ever-growing requirement for more efficient, higher quality display devices. There is significant interest in OLED materials which emit light via a thermally activated delayed fluorescence (TADF) mechanism[1] that converts dark, triplet excited states to emissive singlet states by reverse intersystem crossing (rISC). This can be achieved using aromatic donor–acceptor (D–A) molecules, which typically are conjugationally separated with the D and A units orthogonal. These systems emit from a singlet charge transfer state (¹CT), which is energetically very close to its ³CT state through minimized electron exchange. A further excited state such as a local excited triplet state (³LE) situated very close in energy to this ¹CT is also required.[2] Therefore, having a small singlet–triplet gap (ΔEₘ) is crucial, but is not the only requirement for efficient rISC. rISC can harvest up to 100% of triplet states into singlet states.[3] Currently, the main challenges facing the TADF community are the long overall residence times of emitter molecules in triplet excited states, and the low oscillator strengths of the ¹CT radiative transitions. Here, we report a new TADF molecular design, incorporating a rigid, planar, central donor unit with multiple acceptor units bound via C–N bridges. This new design gives a key step forward in TADF efficiency through multiple coupled singlet–triplet states. The resulting fast rISC rates lead to delayed fluorescence (DF) emission lifetimes shorter than the phosphorescence lifetimes of most Ir complexes currently used in OLEDs.[4] Critically, a unity photoluminescence quantum yield (PLQY) is also maintained.

Recent research has shown that the underlying spin–flip mechanism in rISC is a second order spin–vibronic process.[2,5] Here, specific molecular vibrations promote mixing between a manifold of singlet and triplet states driving efficient rISC. Other vibrational modes can contribute more to nonradiative decay, requiring careful molecular design.[6] Gibson and Penfold have recently published further work detailing this process.[7] Previously synthesized, 1-substituted phenothiazine (D) D–A–D

DOI: 10.1002/advs.201700989
TADF candidates show molecular restriction with several conformers in solution on the $^1$H NMR timescale.[8] As well as the phenothiazine donor being tilted, it is clear that there is some rotational restriction around the C–N bond in these systems, which switches off TADF due to a lack of vibronic coupling. The conformation of the phenothiazine with respect to the acceptor is also important in these molecules.[9] All of the above factors must be taken into account when considering new molecular designs. Another key challenge in the design of TADF molecules is to balance the rates of rISC (and intersystem crossing, ISC)[7] with the fluorescence quantum yield ($\Phi_F$). Ideally, the desired molecule should have a $\Phi_F$ close to 1 with a short emissive state lifetime. This requires strong coupling of the 1CT to the ground state. However, to ensure near degenerate 1CT, 3CT, and 3LE states (which is a requirement for efficient rISC), D–A orthogonality is required. This effectively decouples the 4CT states from the ground state. Therefore, either a compromise is required, or nonradiative quenching to the ground state, i.e., internal conversion, must be dramatically curtailed. The new TADF molecule based on a triazatruxene central donor functionalized with three peripheral acceptors, TAT-3DBTO$_2$ (Scheme 1) is now shown to overcome many of the issues faced when designing an efficient TADF emitter.

2. Results and Discussion

2.1. Synthesis and Chemical Characterization

The design of TAT-3DBTO$_2$ (Scheme 1) is based upon the reversal of the donor and acceptor motif typically found in current TADF emitters.[10] Tri-PXZ-TRZ was prepared by Tanaka et al. and has a central triazine acceptor unit and three peripheral phenoxazine donor units; this work shows the benefits of symmetry as the PXZ-TRZ and bis-PXZ-TRZ analogs showed lower device efficiency compared to the C$_3$ symmetric Tri-PXZ-TRZ. In TAT-3DBTO$_2$ the threefold C$_3$ symmetry is maintained, as in Tri-PXZ-TRZ, but the donor is a central triazatruxene core (TAT). Onto this, three dibenzothiophene-S,S-dioxide units are attached via the nitrogen atoms of the core. Dibenzothiophene-S,S-dioxide was selected as the acceptor in an attempt to match the energy of the 3LE triplet level of the donor to the 1CT energy level. This takes into account that triazatruxene is more electron rich than carbazole due to the central 1,3,5-trinitrogen-substituted benzene core, and is also more conjugated, giving a smaller $\Delta E_{ST}$ and faster rISC rate with dibenzothiophene-S,S-dioxide acceptors. Correctly functionalized TAT derivatives can also exhibit high PLQYs.[11] The synthesis and characterization of TAT-3DBTO$_2$ is shown in Scheme 1 and Sections S1–S4 (Supporting Information).

TAT-3DBTO$_2$ was synthesized in 40% yield and has good solubility in various organic solvents, allowing for efficient synthesis and purification of the molecule. This is an efficient synthesis considering that three Buchwald–Hartwig couplings were performed within one overnight reaction.

The $^1$H NMR spectrum of TAT-3DBTO$_2$ at room temperature (298 K) shows a mixture of broad and sharp peaks, suggesting that parts of the molecule are rotating slowly on the NMR timescale, giving rise to multiple environments for the same protons. This has been shown to be the case by using variable temperature (VT) $^1$H NMR, see Figure 1, and further 2D NMR experiments in the Figures S5–S9 (Supporting Information).

The VT NMR data in combination with pure shift $^1$H NMR studies (Figure S6, Supporting Information) show that there are different conformers of TAT-3DBTO$_2$ in solution; and $^1$H rotating frame nuclear Overhauser spectroscopy (ROESY) NMR experiments (Figure S9, Supporting Information) confirm that these conformers all interconvert between each other. The VT $^1$H NMR data indicate that there is an energy barrier to

![Scheme 1. The synthesis of TAT-3DBTO$_2$ via Buchwald–Hartwig coupling conditions.](image-url)

![Figure 1. Temperature dependent solution state $^1$H NMR spectra of TAT-3DBTO$_2$ in dimethylsulfoxide-d$_6$ (DMSO-d$_6$).](image-url)
Crystallization of TAT-3DBTO₂ was challenging, although single crystals suitable for X-ray analysis were obtained (Figure 2). It is suggested that crystal packing (see Section S11 in the Supporting Information) is responsible for the obtained structure having all acceptor units on the same face of the donor plane. In coevaporated amorphous films, many different conformations of the molecule should coexist. The ground state D–A dihedral angles range from 58° to 62°, significantly less that 90°, which is very much in line with one of the current most efficient TADF materials for green OLEDs, 1,2,3,5-tetrakis(carbazol-9-yl)-4,6-dicyanobenzene (4CzIPN).[12]

2.2. Quantum Chemistry Studies

Figure 3 shows the ten possible conformers of TAT-3DBTO₂, all of which are within 0.03 eV of each other, reflecting the results from the VT ¹H NMR studies (Figure 1). The different conformations consist of different combinations of acceptor orientations with respect to the donor moiety.

2.2.1. Electronic Structure—Absorption

The absorption spectrum of TAT-3DBTO₂ has been computed in the gas phase including the twenty lowest singlet and triplet states. The absorption spectrum exhibits three dominant peaks.
(see Section S13 in the Supporting Information) at 410, 350, and 290 nm. The intensity of each peak increases with higher energy and there is reasonable agreement with the experimental spectrum shown in Figure 4. The molecular conformation has negligible effect on the position, intensity, or character of the transitions and all of the excited states computed exhibit charge transfer character from the donor core to the acceptor moieties, as shown by the density difference plots for each state shown in Section S13 (Supporting Information). The first absorption peak is composed of six pairs of singlet and triplet states of the same character all lying within 0.3 eV of each other. The difference densities associated with each transition are shown in Section S13 (Supporting Information). Because of the C₃ symmetry at this geometry, the states T₂ and T₃ (S₂ and S₃) as well as states T₅ and T₆ (S₅ and S₆) are degenerate. At the ground state equilibrium geometry, the molecular dipole moment is found to be between 1 and 11 D depending on the conformer (see Figure 3).

2.2.2. Electronic Structure—Emission/Relaxation

The emission energy for each conformer is simulated by optimizing the lowest singlet and triplet states. In each case, a rotation of one acceptor moiety to become nearly orthogonal with respect to the donor core is observed. This motion allows minimization of the overlap between the orbitals involved in the excitation and therefore decreases the singlet–triplet energy gap (ΔE[T₁/S₁] = 0.01 eV). The minimum energy geometry of both S₁ and T₁ is very similar (0.001) as is their oscillator strength of 0.0007, as expected by the similar lifetime of the prompt emission in both molecules. Consequently, from these quantum chemistry simulations, it would appear that the enhanced performance of TAT-3DBTO₂ is primarily associated with the enhanced rISC rate derived from the higher density of states.

2.3. Photophysical Properties

2.3.1. Solution Properties

Figure 4a shows the extinction coefficient spectra of TAT-3DBTO₂ and the individual D and A units in dichloromethane (CH₂Cl₂). By comparison to the individual D and A units, the extinction coefficient at all wavelengths is greatly enhanced in TAT-3DBTO₂. This increase in absorption intensity strongly reflects the higher density of states predicted from the quantum chemical calculations described above. Particularly, the absorption band at lower energy (350–425 nm), which is not observed in the D or A units, and is ascribed to a direct absorption from the CT states, is very strong in this new material. Figure S15 (Supporting Information) shows a slight redshift on the right edge of the spectra.
by increasing the polarity of the solvent, which is associated with a strongly mixed \( n \rightarrow \pi^* / \pi \rightarrow \pi^* \) character transition,\cite{13} also confirmed by its relatively strong transition. Excitation into this band directly populates \(^1\)CT excited states, as we have shown in the analogous D–A–D system \( \text{DPTZ-DBTO}_2 \).<!--

Figure 4b shows the photoluminescence (PL) spectra of \( \text{TAT-3DBTO}_2 \) in different solvents together with the separated D and A units in toluene solution. The spectra show clear and strong CT emission, displaying a Gaussian band shape and strong redshift compared to the individual D and A emission spectra. The PL spectra shift to longer wavelengths upon increasing the solvent polarity. This indicates strong positive solvatochromism, as observed in other D–A–D-type molecules.\cite{14,14a} -->

### 2.3.2. Solid State Properties

BCPO, \( \text{(bis-4-[(N-carbazolyl)phenyl]phenylphosphine oxide)} \)\cite{15} was used as a host for \( \text{TAT-3DBTO}_2 \) to maintain the low energy splitting between \(^1\)CT and \(^3\)LE with correct host polarity. The polarity of the P=O bond in BCPO redshifts the \(^1\)CT energy compared to 1,3-bis(N-carbazolyl)benzene (mCP) matrix. The \(^1\)CT is tuned so that it is very close in energy to the \(^3\)LE state. Tuning the \( \Delta E_{ST} \) in such a fashion has previously been demonstrated in the literature. The correct host polarity in this context is defined as a host with a polarity that will minimize the \( \Delta E_{ST} \).\cite{14a,14b} Furthermore, a PLQY of approximately unity was obtained from evaporated films of \( \text{TAT-3DBTO}_2 \cdot \text{BCPO} \) (see Section S16 in the Supporting Information).

Three different emission decay regimes are observed, Figure 5a: region I is fast decay, associated with prompt CT emission (PF); region II is early time DF; and region III is long-lived DF. The PF decay curves show no temperature dependence, indicating negligible migration of the singlet \(^1\)CT excited state. The decay curve at 320 K was fitted using a biexponential function: \( \tau_1 = 10 \text{ ns} \) \((I_1 = 4.4)\) and \( \tau_2 = 35 \text{ ns} \) \((I_2 = 1.2)\). Consequently, \( \tau_{\text{average}} = 22.4 \text{ ns} \) for region I (see Section S17 in the Supporting Information). Region II shows strong TADF, the DF emission increasing in intensity with increasing temperature. The decay times related to region II are \( \tau_1 = 103.9 \text{ ns} \) \((I_1 = 42 777)\), \( \tau_2 = 3.2 \mu\text{s} \) \((I_2 = 112 066)\), and \( \tau_3 = 15.1 \mu\text{s} \) \((I_3 = 61 040)\). Consequently, \( \tau_{\text{average}} = 11.7 \mu\text{s} \) for region II (see Section S17 in the Supporting Information). Usually, DF lifetimes of TADF emitters are in the microsecond timeframe, whereas \( \text{TAT-3DBTO}_2 \) has a DF component with a lifetime on the order of 100 ns, which is a result of fast rISC. Hofbeck and Yersin showed that \( \text{fac-Ir(ppy)}_3 \) has multiple component emission lifetimes \((\tau_1 = 200 \text{ ns}, \tau_2 = 6.4 \mu\text{s}, \tau_3 = 116 \mu\text{s})\).\cite{14} The fastest delayed component of \( \text{TAT-3DBTO}_2 \) emission (103.9 ns) is faster than any emission component from \( \text{fac-Ir(ppy)}_3 \). This demonstrates that fast emission can be achieved without the need of a heavy metal.

As the PLQY for \( \text{TAT-3DBTO}_2 \) in BCPO is \( \approx 1 \), this is not a quenched component, and from its fit weighting it represents \( \approx 20\% \) of all the delayed emissions. This complex multicomponent DF decay is ascribed directly to the multiple conformational possibilities in \( \text{TAT-3DBTO}_2 \). Region III has an inverse temperature dependence: the intensity of the emission increases as the system temperature drops. This has been observed before in highly efficient TADF molecules, and is associated with longer-lived DF components and phosphorescence (PH) at low temperatures.\cite{14a}

The reverse intersystem crossing rates \( (k_{\text{ISC}}) \) of \( \text{TAT-3DBTO}_2 \cdot \text{BCPO} \) film (320 K) were calculated using two different approaches (see Section S18 in the Supporting Information). Three different values of \( k_{\text{ISC}} \) were calculated (see Table 1), each value is associated with a distinct lifetime of DF in a \( \text{TAT-3DBTO}_2 \cdot \text{BCPO} \) film. The fastest lifetime of the DF emission \( (\tau_1 \text{ in region II}) \) gives very high \( k_{\text{ISC}} = 10^7 \text{ s}^{-1} \). Both the \( k_{\text{ISC}} \) calculation methods show good agreement. Calculating the ISC rate, \( k_{\text{ISC}} \) using \( \Phi_{\text{ISC}} = \tau_{\text{prompt}} \cdot k_{\text{ISC}} \) (using the data from Section S18 in the Supporting Information) yields \( k_{\text{ISC}} = 3.5 \times 10^7 \text{ s}^{-1} \). Taking the fastest \( k_{\text{ISC}} = 1.5 \times 10^7 \text{ s}^{-1} \) (see Section S18 in the Supporting Information), we see that \( k_{\text{ISC}} = k_{\text{ISC}} \) and so it is not surprising that the TADF becomes so efficient. The recycling rate of singlet to triplet and back approaches 1 in this case, indicative of very fast and efficient rISC.\cite{14} Figure 5b shows the area-normalized emission spectra in region I at 320 K. The PH emission shows a continuous dynamic redshift. This redshift is associated with the energetic relaxation of the \(^1\)CT state, primarily due to rotation about the D–A bond. Calculations and experiments suggest the D and A units twist toward a more orthogonal geometry, and stabilize in around 70 ns. Region II (Figure 5c) shows stabilized \(^3\)CT emission at 320 K: the onset of each spectrum collected in this region is at \( 2.78 \pm 0.02 \text{ eV} \). The intensity dependence of the DF emission in this region as a function of the laser excitation dose was found to be linear with a gradient of 1, indicative of TADF (see Section S19 in the Supporting Information). Figure 5d shows late time decay (weak emission). Between 70 and 400 \( \mu\text{s} \) (still exponential decay), emission as in region II is observed. From 400 \( \mu\text{s} \) to 10 ms (power law decay), very weak emission is detected. Likely, this region includes DF emission from additional conformers and weak PH emission.

Spectral analysis at 80 K was performed to identify the PH emission. The harvesting of triplet states to singlet states in BCPO host is so rapid that obtaining a clear PH spectrum is problematic. This is due to residual \(^1\)CT emission masking the very weak PH emission. Therefore, the PH spectrum was measured in mCP. In this host the \( \Delta E_{ST} \) is larger \((0.21 \pm 0.03 \text{ eV})\), allowing the PH spectrum to be clearly identified at low temperature \((80 \text{ K})\) (see Section S20 in the Supporting Information). The \( \text{TAT-3DBTO}_2 \cdot \text{mCP} \) PH spectrum was also compared to the PH spectrum collected in polyethylene oxide matrix, and both the spectra show the same onset energy (see Section S20 in the Supporting Information).

Figure 5e shows the PH spectrum of \( \text{TAT-3DBTO}_2 \cdot \text{mCP} \) film and the A and D units. The PH spectrum of \( \text{TAT-3DBTO}_2 \) shows mostly \(^3\)LE character from the acceptor units, while a peak around 550 nm is strongly enhanced. Comparison of the phosphorescence vibronic intensities may indicate a perturbed geometry for the LE triplet state in \( \text{TAT-3DBTO}_2 \) compared to the isolated acceptor unit. Considering that the \(^3\)LE states are almost unaffected by the polarity of the host environment, the triplet levels of \( \text{TAT-3DBTO}_2 \) doped into BCPO will have onsets very close to those observed in mCP and polyethylene oxide.

Figure 5f shows the PH spectrum together with the PL spectrum of \( \text{TAT-3DBTO}_2 \cdot \text{BCPO} \) film, for better comparison. The \(^1\)CT and \(^3\)LE states have onset energies of 2.78 \( \pm 0.02 \text{ and} \)
2.75 ± 0.02 eV, respectively, leading to $\Delta E_{ST} = 0.03 \pm 0.03$ eV. Therefore, it is clear that for TAT-3DBTO$_2$ in BCPO host, the $^1$CT state energy lies very close to the triplet states, as required for fast rISC and highly efficient TADF. However, we also note that there are twelve states very close in energy (described above), which would also couple to mediate rISC.

2.4. OLED Performance

BCPO is an ideal ambipolar host for TAT-3DBTO$_2$, yielding the minimal $\Delta E_{ST}$ and a PLQY of ≈100%. Optimization studies concerned finding the best guest-host ($x$:$y$) ratios. Therefore, two different device architectures were used: one designed for optimization of maximum external quantum efficiency

$$rISC \text{ rates determined from the three exponential decays from TAT-3DBTO}_2:\text{BCPO film using approach a (}{k^a_{\text{isc}}}{)} \text{ and approach b (}{k^b_{\text{isc}}}{)} \text{ for comparison.}$$

(EQE) values (OLED 1) and the another aiming for low roll-off (OLED 2). For optimization of maximum EQE, a lower amount of TAT-3DBTO₂ was coevaporated with BCPO host, 1:9 v/v, and for optimization of roll-off the ratio of TAT-3DBTO₂ to host was higher (1.7:8.3). The architecture of the optimized devices was: indium-tin-oxide (ITO)/NPB(40 nm)/TCTA(10 nm)/TAT-3DBTO₂:BCPO(x:y,30 nm)/TPBi(40 nm)/LiF(1 nm)/Al 100 nm). NPB (N,N′-bis(naphthalen-1-yl)-N,N′-bis(phenyl)-benzidine) and TCTA (tris(4-carbazol-9-ylphenyl)amine)) were used as commercial hole transport layers, TPBi (1,3,5-tris(N-phenylbenzimidazol-2-yl)benzene) as electron transport layer, LiF (lithium fluoride) as electron injection layer, and Al (aluminum) was used as cathode.

Figure 6a shows the green electroluminescence (EL) spectra of both the devices collected at 10 V. The Commission Internationale de L’Éclairage xy chromaticity coordinates for these EL spectra are (0.26, 0.46) and (0.29, 0.50) for OLED 1 and OLED 2, respectively. The emission from OLED 2 is slightly redshifted, which is likely associated with the increase in the overall polarity of the emissive layer induced by the increased TAT-3DBTO₂ concentration.

Figure 6b shows representative EQE versus brightness curves. OLED 1 shows a maximum EQE value of 30.9% (76 cd m⁻²). Given this high EQE value, and the fact that the PLQY was found to be ≈100%, it can be concluded that the device has a charge balance (γ) close to unity. This implies that all the triplet excitons are harvested to singlet states, (ηST = 1), assuming an outcoupling efficiency (ηout) of ≈0.3 (see Section S21 in the Supporting Information). At 1000 cd m⁻², OLED 1 shows an EQE above 15%, exhibiting good resistance to roll-off with maximum brightness values up to 10 000 cd m⁻² (EQE = 4.4%). By increasing the concentration of TAT-3DBTO₂ molecules in the emissive layer (OLED 2), the maximum EQE value drops to 20.2% (74 cd m⁻²), but significantly lower efficiency roll-off is observed. At 10 000 cd m⁻², OLED 2 shows an EQE of 8.8%, with brightness levels reaching 18 410 cd m⁻² (EQE = 3.9%).

Figure 6c shows the current density versus voltage. Both OLEDs show very low turn-on voltages of ≈2.5 V. However, in OLED 1, this value is slightly lower, which may be associated with the fact that TAT-3DBTO₂ molecules are not as ambipolar as BCPO, so by decreasing its concentration, a better J–V curve (lower turn-on voltage) is observed. The same explanation holds for the current efficiency (ηc) versus voltage curves (Figure 6d) up to 8 V: both the devices show similar current efficiency (ηc₁,max = 50.8 cd A⁻¹, ηc₂,max = 52.9 cd A⁻¹), although at higher voltages OLED 1 exhibits much better resistance to high current efficiency levels. Table 2 highlights all the electrical properties of these devices and the values of each efficiency at 100 and 1000 cd m⁻², showing their electrical stability.

The reproducibility of these devices with such high EQEs and low roll-offs was studied in more detail (see Section S22 in the Supporting Information). Several other sets of devices with slightly distinct device structures also show EQE values around 30%. Therefore, the data presented in the main paper are the most representative among the OLEDs tested.

3. Conclusion

In conclusion, TAT-3DBTO$_2$ introduces a new design for TADF emitters. The multi-acceptor single-donor motif imparts a large number of energy states which gives a short prompt 1CT lifetime and unitary PLQY. Moreover, we find 12 singlet–triplet state (pairs) within 0.2 eV of each other, which we believe gives rise to a DF component with a very fast rISC rate, on the order of $1 \times 10^7$ s$^{-1}$. This shows that it is possible to achieve both a unitary PLQY and a sub-microsecond TADF lifetime in the same molecule. The conformational complexity of the molecule, however, gives rise to different rISC rates, as observed in the emission decays. Nevertheless, in devices, these optimal photophysical properties translate into an EQE which exceeds 30% at a useful brightness of 76 cd m$^{-2}$. Thus, this new TADF molecular design opens up a new dimension for achieving truly high performance TADF OLEDs and provides a solution to overcome the main concerns of current TADF molecular designs.

4. Experimental Section

Three types of samples were studied in this work: i) TAT-3DBTO$_2$ solutions ($10^{-3}$–$10^{-2}$ M) in methycyclohexane, toluene, and dichloromethane (CH$_2$Cl$_2$) solvents; ii) drop-cast doped film of TAT-3DBTO$_2$:mCP 1:9 molar ratio; and iii) evaporated doped films of TAT-3DBTO$_2$:BCPO, 1:9 v/v. All the solutions were stirred for several hours to ensure complete dissolution. The films were dispersed onto quartz substrates.

Steady state absorption and emission spectra were acquired using a UV-3600 Shimadzu spectrophotometer and a Jobin Yvon Horiba Fluoromax 3, respectively. Time-resolved spectra were obtained by exciting the sample with a Nd:yittrium aluminium garnet (YAG) laser (EKSPLA), 10 Hz, 355 nm or by using a nitrogen laser, 10 Hz, 373 nm. Sample emission was directed onto a spectrophotograph and gated intensified charged couple device (ICCD) camera (Stanford Computer Optics).

OLED devices were fabricated using the process of OLED deposition chamber at 10 mbar. All commercial organic compounds were previously purified by vacuum sublimation.

Structures were optimized with the Q-Chem quantum chemistry package using the density functional theory (DFT) method with Pople’s 6-31G(d) basis set and the Perdew–Burke–Ernzerhof’s PBE0 functional. Electronic structure calculations were performed using the time-dependent density functional theory (TD-DFT) method with the 6-31G(d) basis set and the PBE0 functional corrected by the Tamm–Dancoff approximation. All calculations were performed in the gas phase.

Acknowledgements

P.L.d.S. and J.S.W. contributed equally to this work. Authors A.P.M., M.R.B., and J.S.W. thank the EPSRC for funding grant EP/L02621X/1. P.L.d.S. thanks the CAPES Foundation, Ministry of Education of Brazil, Science Without Borders Program for a PhD studentship, Proc. 12027/13-8. A.P.M. and T.J.P. thank the EPSRC for funding grant EP/P012167/1, EP/P012388/1. J.S.W. and D.G.C. designed the original molecule, devised and performed the synthesis, purification, and characterization under the supervision of M.R.B. P.L.d.S. performed all steady state and time-resolved photophysics, device fabrication, and device testing under the supervision of A.P.M. P.L.d.S. and A.P.M. analyzed the optical data. D.G.C. and P.L.d.S. performed and analyzed the electrochemistry study. D.G.C. performed the photoluminescence quantum yield. J.E. and D.G.C. performed calculations under the supervision of T.J.P. The X-ray crystallography was performed by A.S.B. using crystals grown by J.S.W. P.L.d.S., J.S.W., T.J.P., M.R.B., and A.P.M. wrote the main body of the paper and the Supporting Information.

Conflict of Interest

The authors declare no conflict of interest.

Keywords

fast reverse intersystem crossing rates, thermally activated delayed fluorescence (TADF), triazatruxene
