ABSTRACT: Achieving long persistent phosphorescence in polymers is a challenge even at low temperature. In this work, long persistent phosphorescence (> 1 s) is observed in non-conjugated polyurethane derivatives at 77 K, which is among the longest reported phosphorescent lifetimes for an organic polymer. The mechanism for this unusual behavior has been shown by steady-state photophysical characterization and time resolved emission spectra to arise from the formation of intra- and/or intermolecular carbonyl clusters at low temperature. The lifetime of long persistent phosphorescence is increased by the introduction of an aromatic monomer into the non-conjugated polyurethane chains. This is attributed to intra- and/or intermolecular n–π* transitions from electron rich carbonyl groups to the conjugated aromatic units thereby enhancing the intersystem crossing (ISC) rate. Coating an ultraviolet InGaAsN LED with a polyurethane derivative as the emitter gives cryogenic afterglow with long persistent phosphorescence which is observed for up to 7 s with naked eyes.
1. INTRODUCTION

Non-conjugated polymers are emerging as unconventional luminophores which do not possess typical polycyclic π-conjugated chromophoric units, and they have aroused great interest due to their significant academic value and promising technological applications.\(^1\)\(^-\)\(^5\) Compared to the traditional organic luminescent materials, non-conjugated polymers show many advantages in terms of ease of chemical preparation, environmental-friendliness and applications in biological fluorescence imaging, due to their good hydrophilicity, chain flexibility and structural versatility.\(^6\) Research in this area is still in its infancy, lacking clear guidelines for polymer design, and the mechanism of luminescence is not well understood. Generally, the presence of electron rich heteroatoms, such as nitrogen,\(^7\)\(^-\)\(^14\) oxygen,\(^15\)\(^-\)\(^19\) phosphorus,\(^20\)\(^,\)\(^21\) or sulfur,\(^22\)\(^,\)\(^23\) and/or unsaturated C=O,\(^24\) C=C\(^25\) and C≡N\(^26\) subgroups into non-conjugated backbones is necessary for unconventional luminescence. Therefore, it is desirable to develop new types of luminescent non-conjugated polymers and to further probe the mechanism of emission in these systems.

Polyurethanes (PUs) are industrial-scale non-conjugated polymers with many desirable properties, such as facile synthesis, good mechanical toughness, abrasion resistance and low-temperature resistance. They have found broad applications as shape-memory materials, building insulation, components of furniture and fabrics in our daily life.\(^27\)\(^-\)\(^29\) However, their luminescent properties and optoelectronic applications are largely unexplored.\(^30\)\(^-\)\(^33\) We hypothesized that by virtue of the structural flexibility and electron rich heteroatoms (O and N) non-conjugated polyurethanes could possess interesting photophysical properties due to the following considerations. First, the non-conjugated architecture may effectively avoid aggregation-induced quenching of emission which is facilitated by strong π-π stacking interactions in conjugated materials. Consequently efficient emission could occur at high concentrations. Second, the non-conjugated PU structure blocks strong electronic coupling, and is therefore favorable for blue emission. Third, due to the good mechanical flexibility of PUs, the individual polymer chains are in close proximity. Excited state charge transfer processes may, therefore, readily occur through intermolecular interactions, leading to a small singlet–triplet splitting (Δ\(E_{st}\)) which, in turn, could promote intersystem crossing (ISC) as well as reverse ISC (RISC)\(^34\) between singlet (S\(_1\)) and triplet (T\(_1\)) states, thus prolonging the exciton lifetimes.

In this work, a series of three non-conjugated polyurethanes PU1–PU3 have been rationally designed: PU1 incorporates the classical π-aromatic binaphthyl chromophores, whereas PU2 and PU3 have π-aromatic biphenyl chromophores and non-aromatic units, respectively, in the polymer backbones. PU1–PU3 all show unusually long persistent luminescence (LPL) at 77 K - including PU3 with no aromatic backbone units. There is an increase in luminescent lifetimes with the introduction of aromatic monomer units, indicating that the LPL lifetimes can be rationally tuned by the incorporation of aromatic chromophores into these PU derivatives. Thus, among the three PUs, PU1, exhibits the longest phosphorescent decay times of 1.4 s and 0.52 s in solution and powder states, respectively. Steady-state photophysical data and time resolved emission spectra (TRES) lead to the conclusion that the formation
of intra- and/or intermolecular carbonyl clusters at low temperature plays a key role in obtaining long persistent phosphorescence. These results, therefore, establish that polyurethane derivatives can be designed to display aggregation-induced persistent phosphorescence. Furthermore, benefiting from the excellent LPL at high concentration for PU1, a cryogenic afterglow InGaAsN light-emitting diode (LED) has been fabricated using PU1 as the emitter. Long persistent phosphorescence is observed for up to 7 s by naked eyes.

2. RESULTS AND DISCUSSION

Synthesis. The PUs were synthesized by dissolving polyethylene glycol mono-methyl ether (Mn 200 g mol⁻¹, 0.396 g, 1.98 mmol) and either (R)-1-(2-hydroxynaphthalen-1-yl)naphthalen-2-ol ((R)-BINOL) (2.62 mmol), or 2,2′-biphenol (2.62 mmol), or 1,2-ethanediol (2.62 mmol) in anhydrous THF (10 mL). Hexamethylene diisocyanate (0.608 g, 3.61 mmol) and 1,4-diazabicyclooctane triethylenediamine (DABCO) (12 mg, 0.06 mmol) were then added to the reaction mixture which was stirred at 75 ºC for 7 h under N₂ until the clear solution became viscous, indicating polymerization had occurred. After cooling to room temperature, excess diethyl ether was added to precipitate the products PU1 (Mn = 3118 g mol⁻¹), PU2 (Mn = 1845 g mol⁻¹) and PU3 (Mn = 3544 g mol⁻¹), respectively, with yields >60% (Scheme 1). The detailed synthetic methods and ¹H NMR and FTIR spectroscopic characterization are given in the experimental section and supporting information.

Physical Properties. Most aggregation-induced emission (AIE) materials are almost non-emissive in both dilute and highly concentrated solutions, whereas bright emission can be observed in the solid and host-guest doped film states due to the restriction of intramolecular motion (RIM). At room temperature, PU1–PU3 show faint emission in dilute solution, whereas intense emission is observed in highly concentrated solution and in the solid states, which is atypical AIE behavior. The absorption spectra of PU1 in different ratios of acetone–water mixtures are depicted in Figure S5a. The major absorption peak at 339 nm is assigned to the R band of an n→π* transition, suggesting that O, and/or N atoms are conjugated with aromatic rings in the system. The progressively enhanced absorption intensity with an extended red edge for increased water% is evidence for the formation of nano-aggregates, which was further established by transmission electron microscopy (TEM) results. The TEM image of PU1 showed dispersed nanoparticles with a diameter in the range of 20–50 nm in dilute acetone solution (1 × 10⁻⁵ M) (Figure S6a). However, when the add-
ed water fraction reached 90%, irregularly shaped (chains and particles) larger aggregates were formed (Figure S6d). This indicates that nano-aggregation is enhanced by the addition of water which is a poor solvent.

The corresponding emission spectra of PU1 in different ratios of acetone–water mixtures are shown in Figure 1a. PU1 exhibits faint emission in dilute acetone solution ($10^{-5}$ M), which is considerably increased when the water fraction exceeds ca. 60%. Emission peaks at 373, 410, 447, 479, 513 and 561 nm with different lifetimes ($\tau$) of 1.1, 1.24, 6.32, 6.7 and 6.64 ns are observed. Meanwhile, the emission spectrum of monomer (R)-BINOL was also measured in both the solution and powder states (Figure S7) and only UV emission with a peak at 370 nm was observed. This indicates that the emission peak at 373 nm in PU1 originates from the excited state of the (R)-BINOL unit. The other emission peaks of PU1 are indicative of the presence of different emissive species in solution, derived from various aggregated structures owing to chain folding and aggregation. When the water fraction increases up to 90%, 100-fold increase in emission intensity of PU1 was observed in comparison with the pure acetone solution. The photoluminescence quantum yield (PLQY) of PU1 is 21%. All the above photophysical results demonstrate that PU1 displays AIE.

![Figure 1](image.png)

**Figure 1.** (a) Emission spectra of PU1 ($1 \times 10^{-5}$ M) in acetone–water mixtures with different water fractions (0–90% v/v) at room temperature. Inset: photographs of PU1 ($M_n$ 3118 g mol$^{-1}$) in pure acetone solution and acetone–water mixture ($f_w = 90\%$) under 365 nm UV illumination. (b) PL spectra of PU1/acetone with different concentrations. Inset: photographs taken under 365 nm UV light.

In contrast to the typical AIE effect, a concentration dependent emission behavior was observed for PU1 in acetone solution (Figure 1b). The concentrations of PU1 were selected within the range of $1 \times 10^{-5}$ M – $2 \times 10^{-4}$ M. The emission intensity of PU1 increases when the concentration increased to $1 \times 10^{-4}$ M and shows similar emission features to the acetone/water mixtures at low concentration of $1 \times 10^{-5}$ M. Meanwhile, the similar features in the UV-vis absorption spectra of PU1 in acetone (Figure S5b) to the acetone–water mixtures (Figure S5a) demonstrate that the aggregates form in both conditions. TEM reveals that the sizes of nanoparticles increased from ca. 20 nm to ca. 200 nm with an incremental increase in concentration ($10^{-5}$ M – $2 \times 10^{-4}$ M) of PU1 (Figures S6a-c). To investigate the possible influence of hydrogen bonding interactions in the aggregated state, $^1$H NMR spectra were recorded for concentrations of 2.5 mg mL$^{-1}$ and 5 mg mL$^{-1}$ of PU1 in DMSO-$d_6$. The almost identical $^1$H NMR spectra for both solutions (Figure S8) with no N-H shift, implies that hydrogen bonding interactions are absent or very weak in the aggregated state. Thus, it is rational to ascribe the AIE mechanism of PU1 to the formation of carbonyl clusters. As illustrated in Figure 2,
the linear PU1 chains will be extended in dilute solution, effectively isolating the carbonyl groups and, therefore, leading to only faint emission (Figure 2a). In concentrated solution or the aggregated state, PU1 chains will entangle and approach each other in close proximity to form carbonyl clusters, affording through-space electronic overlap between lone pairs and π electrons (Figures 2b and 2c). Consequently, in the more rigidified conformations there is enhanced electronic conjugation, which, in turn, leads to enhanced emission. In previous work the unconventional emission in non-conjugated linear and hyperbranched polymers, e.g. siloxane-poly(amidoamine) dendrimers, was explained by aggregation of multiple carbonyl groups.6,24 LPL of non-conjugated polyacrylonitrile, without any aromatic chromophore in the molecule, has been ascribed to clustering of the pendant cyano groups in concentrated solution and solid samples affording through-space electronic communication.26

![Figure 2. Schematic illustration of PU1 (a) dilute solution, (b) concentrated solution, and (c) carbonyl clusters in the aggregated state.](image)

The emission spectra of PU1 in the powder state were explored at different excitation wavelengths (Figure S9). Under UV illumination powder PU1 exhibits bright emission covering the UV and visible regions. The weak lower energy emission peaks are consistent with those observed in high concentration acetone solution and acetone/water mixtures (Figure 1a), indicating the presence of various emissive species that might be derived from different carbonyl clusters. The semicrystallinity of PU1 shown by powder X-ray diffraction (Figure S10) offers additional physical restraints and is favourable for light emission.26

**Cryogenic long persistent phosphorescence.** The photophysical properties of PU1 were further studied at 77 K in dilute 2-methylTHF solution (10⁻⁵ M). As shown in Figure 3a, upon irradiation with UV light at 365 nm, the steady-state emission spectra showed multiple profiles with major peaks at 409, 437, 463 and 497 nm, which is similar to the behavior at room temperature (Figure 1b). Upon removal of the ultraviolet irradiation, LPL lasting for 2 s with changed emission color was clearly observed by naked eyes (Figure 3a insert images and Supplementary Movie 1). Thus PU1 exhibits LPL which is rarely observed in a non-conjugated polymer.38-41 The resistance of the low temperature phosphorescence to photobleaching was further confirmed by 20 repeated excitation cycles with high reproducibility (Figure S11). To further investigate this rare LPL, transition-state emission spectra (TRES) were obtained. As shown in Figure 3a, the TRES of PU1 showed multiple emission profiles with major peaks at 445, 490, 513 and 560 nm. Decay times corresponding to emission peaks were measured individually. Interestingly, in contrast to the fast fluorescent emission (S₁→S₀) with lifetimes of a few nanoseconds at room temperature, long persistent phosphorescent (T₁) lifetimes beyond a
few hundred milliseconds were observed in each peak (Table S1). The longest luminescent lifetime of 1.4 s was observed in the 560 nm peak (Figure 3b). For comparison, a lifetime of 1.2 s has been reported at room temperature for poly(methylmethacrylate) (PMMA) with an N-substituted naphthalimide end group. Poly(lactic acid) functionalized with difluoroboron dibenzoylethane has a lifetime of 1.75 s at 77 K. Thus, the T1 excited state with long decay times dominates the emission behavior of PU1 at 77 K. It is known that at low temperature, the rates of internal conversion (IC), intersystem crossing (ISC), and collisional quenching are commonly restricted due to the rigidity of the frozen sample, resulting in phosphorescence with microsecond (µs) decay times. However, to the best of our knowledge, such long persistent phosphorescence (~0.8 s) has not been previously reported in an organic polymer at 77 K at a concentration as low as 10⁻⁵ M (Table S1).

![Figure 3](image_url)

**Figure 3.** (a) The steady-state photoluminescence and long phosphorescence spectra of PU1 with different average molecular weights (Mn 2672 or 3118 g mol⁻¹), and different concentrations in 2-MeTHF solutions at 77 K. Insets show the corresponding photographs taken at different times before and after turn-off of the excitation (365 nm) at 77 K. (b) Phosphorescence decays at 560 nm of PU1 in 2-MeTHF solution. (c) The proposed LPL mechanism for PU1 at 77 K.

What is the reason for this unusual LPL phenomenon? Based on the formation of nanoparticles at low concentration (10⁻⁵ M) of PU1, as observed from the TEM image (Figure S6a), we propose that the electron rich heteroatoms and the good flexibility in the polyurethane chains promote the formation of clusters through intra- and/or intermolecular interactions even at this low concentration. This is a different situation from pure small organic molecules that are regarded as isolated molecules without any intra- or intermolecular interactions in dilute solution. The spacial electronic overlap between lone pairs and π electrons within the carbonyl clusters in PU1 explains the fascinating cryogenic long persistent phosphorescence. To validate our hypothesis, PMMA matrices doped with PU1 (2%) were used in solid-state “dilution” experiments to probe the role of intramolecular motions on the observa-
tion of LPL. In contrast to the long phosphorescent lifetime (~0.8 s) observed in the low concentration solutions of pure PU1 at 77 K, a PMMA doped film exhibited a short fluorescent lifetime of 2 ns (Figure S12). This confirms that effectively restricting intramolecular motions is not the reason for the observed LPL of PU1 at 77 K.

Figure 4. 3D time resolved emission spectra (TRES) (left) and corresponding transition-state emission spectra (right) of PU1–PU3 in powder state at 77 K.

More detailed photophysical measurements certify that carbonyl clusters plays a key role in obtaining LPL. Concentration dependent emission data in 2-MeTHF solution are shown in Figure 3b and Table S1. Persistent phosphorescence with $\lambda_{\text{max}}$ at 560 nm was selected, and the decay time of PU1 increased from 0.76 s to 1.44 s upon increasing the concentration from $10^{-5}$ to $10^{-2}$ M. This concentration-promoted LPL is consistent with the formation of clusters. Furthermore, the influence of different degrees of polymerization in PU1 on LPL was also considered by comparing samples with $M_n$ 3118 and 2672 g mol$^{-1}$. The two samples showed similar concentration dependent LPL (Figure 3b and Table S1). It is worth noting that the decay lifetime increases significantly with the increased degree of polymerization (Figure 3b and Table S1). This can be attributed to increased formation of clusters by the more flexible chains and the electron rich heteroatoms of PU1 (3118 g mol$^{-1}$). In contrast to the long phosphorescent lifetime (~0.8 s) observed for PU1 at 77 K, (R)-BINOL exhibited a short phosphorescent lifetime of 8.77 µs in dilute 2-MeTHF
solution (Figure S13). Therefore, all the above results provide substantial evidence that aggregation induced by carbonyl clusters is a key requisite for LPL at 77 K in PU1.

In the powder state of PU1, LPL is also observed for both molecular weight samples ($M_n$ 3118 and 2672 g mol$^{-1}$) at 77 K. The transition-state emission spectra of PU1 show a broad emission band with peaks at 520 and 550 nm (Figures 4a, 4b). LPL behavior of PU1 (3118 g mol$^{-1}$) was observed by naked eyes for a period of 4 s, and the corresponding decay time was 0.52 s. Similar to the solution state, an increased decay time was observed from the lower molecular weight (2672 g mol$^{-1}$, 0.44 s) compared to the higher molecular weight (3118 g mol$^{-1}$, 0.52 s) of powder samples of PU1 (Figure S15 and Table S2, $\lambda_{max}$ 550 nm). The lifetime data for PU1 ($M_n$ 2672 g mol$^{-1}$) in the pristine film state at two different concentrations of 10 mg and 100 mg were also investigated at 77 K. There is an increase in luminescence lifetime with increasing concentration of PU1 (Table S3).

To further probe the LPL mechanism of PU1, the $S_1$ and $T_1$ energy levels were estimated from the onset wavelengths of the 298 K and 77 K steady-state emission spectra (Figure S16), respectively, measured in solution. The small $S_1$-$T_1$ energy gap ($\Delta E_{ST}$ 0.06 eV) could promote the ISC as well as reverse ISC (RISC) processes, thus prolonging the excited state lifetimes. At room temperature, fast fluorescence from the $S_1$ state with a lifetime of a few nanoseconds is observed due to the spin-forbidden $T_1$ state. Meanwhile, thermally activated delayed fluorescence (TADF) was not observed, perhaps due to a lack of spin-vibronic coupling.

At 77 K, assisted by the low temperature, the singlet excitons were rapidly converted to triplet excitons through a fast ISC process, and bright blue phosphorescence was observed in steady-state conditions, and the corresponding $T_1$ energy level was calculated as 3.09 eV (Figure S16). On removal of the ultraviolet irradiation, the emission color changed from blue to green-yellow with a lower energy level of 2.71 eV (Figure S16). This result is evidence for the existence of a stabilized excited state ($T_1$) which functions as an energy trap, and maybe delocalized on several neighbouring polyurethane chains, resulting in long phosphorescence by facilitating radiative pathways and suppressing non-radiative deactivation decays. The proposed LPL mechanism of PU1 is shown in Figure 3c.
Intermolecular n–π* transitions from electron-rich heteroatoms to conjugated (hetero)aromatic units in small molecules have been shown by the groups of Chi,$^{48}$ Li,$^{49}$ Huang$^{50}$ and Tang$^{51-53}$ to facilitate ISC leading to LPL behavior. Recently Li et al. reported that intermolecular π–π interactions play an important role in persistent phosphorescence.$^{54-56}$ Therefore, it is rational to check the role of the aromatic unit in obtaining LPL in our polyurethane system. For comparison with PU1, analogs were prepared with a smaller biphenyl unit (PU2, $M_n = 1845$ g mol$^{-1}$) and with a saturated unit (PU3, $M_n = 3544$ g mol$^{-1}$), replacing the binaphthyl unit of PU1. The luminescence decays of PU2 and PU3 were measured in the powder state at 77 K. As shown in Figures 4c, 4d and Table S2, both PU2 and PU3 exhibit LPL behavior, demonstrating that the aromatic unit is not essential for LPL in polyurethane derivatives. Nonetheless, the decay times clearly increase with the introduction of aromatic units into the non-conjugated PU chains (Table S2), revealing that the intra- or intermolecular n–π* transition from electron rich carbonyl groups to the conjugated aromatic units is favorable for enhancing LPL behavior.

**Cryogenic afterglow LED.** To investigate the potential optoelectronic applications of the polyurethane materials, a cryogenic afterglow LED was fabricated by adding dropwise a solution of PU1 ($M_n 2672$ g mol$^{-1}$) in 2-methylTHF onto an ultraviolet InGaAsN LED chip ($\lambda_{em} = 395$ nm). As shown in Figure 5b, due to the favorable viscosity of the polymer, PU1 (50 mg) uniformly adheres to the surface of the LED to form a thin film. Immediately after removing the LED bulb from the 77 K environment, upon electrical excitation with a low voltage (3 V) bright blue emission was obtained (Figure 5c). When the applied voltage was turned off, green persistent emission is observed for as long as 7 s, attributed to the phosphorescence of PU1 (Figure 5d and Supplementary Movie 2).

### 3. CONCLUSION

In summary, visible long-lived luminescence (> 1 s) in a non-conjugated polyurethane system at 77 K has been reported for the first time. The aggregation-induced LPL mechanism was shown by detailed photophysical and time resolved emission spectra to arise from spacial electronic overlap between lone pairs and π electrons through the formation of carbonyl clusters. The introduction of conjugated aromatic units into the backbone of the non-conjugated polymer chains has been shown to promote the ISC process through intra- or intermolecular n–π* transitions and further increase the decay times of LPL. Furthermore, benefiting from the excellent aggregation-induced LPL, a cryogenic afterglow light-emitting diode (LED) has been fabricated and persistent phosphorescence has been observed for up to 7 s by naked eyes. This work should promote new studies on the rational design of non-conjugated polymers which display aggregation-induced long-lived luminescence, leading to further applications in optoelectronic
technologies. In the future, unconventional ultralong-lived luminescence may be realized by tailoring the structure of a non-conjugated polymer.

4. EXPERIMENTAL SECTION

Synthesis. PU1 was prepared according to the following general procedure: A mixture of (R)-BINOL (0.750 g, 2.62 mmol), polyethylene glycol mono-methyl ether \( M_n = 200 \ \text{g mol}^{-1} \); 0.396 g, 1.98 mmol), anhydrous THF (10 mL), hexamethylene diisocyanate (0.608 g, 3.61 mmol) and DABCO (12 mg, 0.105 mmol) was heated at 75°C for 7 h under a nitrogen atmosphere until the clear solution became significantly viscous, indicating polymerization. After cooling to room temperature, the mixture was precipitated from excess diethyl ether. Then the product was dried under vacuum at room temperature for 24 h to obtain the resulting polymer. Yield: 61%. \(^{1}\)H NMR (500 MHz, DMSO-\(d_6\), \(\delta\) [ppm]): 7.01-8.08 (broad, 12H; (R)-BINOL protons), 4.04 (s, 4H), 3.37-3.58 (broad, PEG protons), 3.32 (s, 6H; PEG terminal -OCH\(_3\) protons), 2.63-2.98 (broad, 4H), 1.09 (broad, 4H), 0.75 (broad, 4H). FTIR: 3339 cm\(^{-1}\)(N-H), 2860 and 2941 cm\(^{-1}\) (-CH\(_2\)- asymmetric and symmetric stretch), 1692 (C=O), 1113 cm\(^{-1}\) (C-O-C stretch PEG). Anal. Calcd for C\(_{40}\)H\(_{86}\)N\(_{10}\)O\(_{11}\):

\[\begin{align*}
\text{C} & : 60.17; \\
\text{H} & : 7.16; \\
\text{N} & : 6.16. \\
M_n & = 3118 \ \text{g mol}^{-1}, \ PDI = 1.52.
\end{align*}\]

The synthetic procedure for PU2 was the same as PU1, except monomer 2,2'-biphenol (0.488 g, 2.62 mmol) was used instead of (R)-BINOL. Yield: 63%. \(^{1}\)H NMR (500 MHz, DMSO-\(d_6\), \(\delta\) [ppm]): 7.02-7.44 (broad, 8H; 2,2'-biphenol protons), 4.03 (s, 4H), 3.40-3.60 (broad, PEG protons), 3.32 (s, 6H; PEG terminal -OCH\(_3\) protons), 2.88 (broad, 4H), 1.16 (broad, 4H), 1.32 (broad, 4H). FTIR: 3327 cm\(^{-1}\)(N-H), 2858 and 2933 cm\(^{-1}\) (-CH\(_2\)-asymmetric and symmetric stretching), 1715 cm\(^{-1}\) (C=O), 1111 cm\(^{-1}\) (C-O-C stretching PEG). Anal. Calcd for C\(_{38}\)H\(_{70}\)N\(_{10}\)O\(_{13}\):

\[\begin{align*}
\text{C} & : 61.13; \\
\text{H} & : 7.77; \\
\text{N} & : 7.51. \\
M_n & = 1845 \ \text{g mol}^{-1}, \ PDI = 1.16.
\end{align*}\]

The synthetic procedure of PU3 was the same as PU1, except monomer 1,2-ethanediol (0.163 g, 2.62 mmol) was used instead of (R)-BINOL. Yield: 64%. \(^{1}\)H NMR (500 MHz, DMSO-\(d_6\), \(\delta\) [ppm]): 7.16 (s, 2H), 4.06 (broad, 4H), 3.93 (broad, 4H), 3.41-3.58 (broad, PEG protons), 3.32 (s, 6H; PEG terminal -OCH\(_3\)- protons), 2.94 (s, 4H), 1.35 (s, 4H),1.22 (s, 4H). FTIR: 3326 cm\(^{-1}\)(N-H), 2862 and 2939 cm\(^{-1}\) (-CH\(_2\)- asymmetric and symmetric stretching), 1684 cm\(^{-1}\) (C=O), 1144 cm\(^{-1}\) (C-O-C stretching PEG). Anal. Calcd for C\(_{38}\)H\(_{70}\)N\(_{10}\)O\(_{13}\):

\[\begin{align*}
\text{C} & : 60.17; \\
\text{H} & : 7.52; \\
\text{N} & : 7.80; \\
O & : 24.51. \\
\end{align*}\]

The \(M_n\) of PU3 is 3544 g mol\(^{-1}\) calculated from the \(^{1}\)H NMR spectra.

Photophysical Characterization. UV-vis absorption spectra were recorded on a Shimadzu UV-3100 spectrophotometer. Steady-state emission spectra, the excited-state lifetimes (\(\tau\)), photoluminescence quantum yields (\(\Phi_p\)) and time resolved emission spectra (TRES) were recorded on an Edinburgh FLS-920 spectrofluorimeter equipped with a xenon arc lamp (Xe900), a nanosecond hydrogen flash-lamp (nF920) and a microsecond flash-lamp (\(\mu\)F900), respectively. For fluorescence decay measurements, subnano-second optical pulses over the VUV-to-NIR spectral range were provided using a hydrogen flash lamp. The microsecond flash lamp
produces short, typically a few μs, and high irradiance optical pulses for phosphorescence decay measurements in the range from microseconds to seconds. The lifetimes (τ) of the luminescence were obtained by fitting the decay curve with a multi-exponential decay function where

\[ I(t) = \sum_{i} A_i e^{-t/\tau_i} \]

\( A_i \) and \( \tau_i \) represent the amplitudes and lifetimes, respectively, of the individual components for multi-exponential decay profiles.

**Fabrication of cryogenic afterglow LED.** A cryogenic afterglow light-emitting diode (LED) was fabricated by dropwise addition of a solution of PU1 \( (M_n 2672 \text{ g mol}^{-1}, 50 \text{ mg, 3.5 wt\%}) \) in 2-methylTHF on an ultraviolet InGaAsN LED chip \( (\lambda_{\text{em}} 395 \text{ nm}) \) at room temperature. The photographs and supporting movies were recorded with a cell phone (HUAWEI Nova 1).

1. Experimental - general information

Materials obtained from commercial suppliers were used without further purification unless otherwise stated. All glassware, syringes, magnetic stirring bars, and needles were thoroughly dried in a convection oven. $^1$H NMR spectra were recorded at 25 ºC on a Varian 500 MHz spectrometer. The $^1$H NMR spectra were referenced internally to the residual proton resonance in DMSO-$d_6$ ($\delta$ 2.5 ppm). The molecular weights of the polymers were determined by gel permeation chromatography (GPC) on a Waters 410 instrument with monodispersed polystyrene as the reference and THF as the eluent at 35 ºC. The $M_n$ values for all PUs were also calculated from $^1$H NMR spectra. For PU1 and PU2, the calculated values from $^1$H NMR were consistent with the data measured from GPC to within 300 g mol$^{-1}$. Transmission electron microscopy (TEM) was performed using a TECNAI F20 microscope. The samples were prepared by placing microdrops of the solution on a holey carbon copper grid. UV-vis absorption spectra were recorded on a Shimadzu UV-3100 spectrophotometer. Photoluminescence spectra were collected on an Edinburgh FLS920 spectrophotometer. IR spectroscopy was conducted using KBr pellets with an Nicolet 6700 FT/IR spectrophotometer ranging from 4000 to 400 cm$^{-1}$. Powder X-ray diffraction (XRD) patterns of the samples were collected on a Rigaku Dmax 2000.

2. Structural characterization

To investigate the effect of the degree of polymerization on LPL, different chain length samples of PU1 and PU2 were also synthesized by the same synthetic route as for PU1 and PU2 ($M_n$ = 3118 and 1845 g mol$^{-1}$). The $M_n$ values for the new PU1 and PU2 samples were measured as 2672 g mol$^{-1}$ and 2204 g mol$^{-1}$, respectively, from GPC.
Figure S1. $^1$H NMR spectrum of PU1 in DMSO-$d_6$ (* indicates peaks from the solvent and water)

Figure S2. $^1$H NMR spectrum of PU2 in DMSO-$d_6$ (* identifies peaks from solvent and water)
Figure S3. $^1$H NMR spectrum of PU3 in DMSO-$d_6$ (* indicates peaks from the solvent and water).

Figure S4. FTIR spectra of PU1, PU2 and PU3.
3. Photophysical properties

**Figure S5.** (a) UV-visible absorption spectra of PU1 in acetone-water mixtures with different water fractions (0–90%, v/v) at room temperature. (b) UV-visible absorption spectra of PU1/acetone at different molar concentrations.

**Figure S6.** TEM images of nanoaggregates of PU1 formed in (a) acetone solution (10⁻⁵ M), (b) acetone solution (10⁻⁴ M), (c) acetone solution (2 × 10⁻⁴ M) and (d) acetone–H₂O mixtures with 90% water fraction (10⁻⁵ M).
**Figure S7.** PL spectra of monomer (R)-BINOL (black lines) and PU1 (blue lines) at room temperature.

**Figure S8.** $^1$H NMR spectra of PU1-2.5 mg/mL and PU1-5 mg/mL in DMSO-$d_6$. 
3. Photophysical Properties
