Photoelectron spectroscopic study of $\Gamma^-\cdot$ICF$_3$: A frontside attack $S_n2$ pre-reaction complex

Golda Mensa-Bonsu,$^a$ David J. Tozer$^a$ and Jan R. R. Verlet$^b$

Photodetachment and 2D photoelectron spectra of the mass-selected $\Gamma^-\cdot$CF$_3$ complex are presented together with electronic structure calculations. Calculations show that the $\Gamma$ is located at the iodine side of CF$_3$. Vertical and adiabatic detachment energies were measured at 4.03 and approximately 3.8 eV, respectively. The photoelectron spectra and molecular orbitals show a significant covalent bonding character in the cluster. The presence of electronic excited states is observed. Below threshold, iodide is generated which can be assigned to the photoexcitation of degenerate charge-transfer bands from the off-axis $\pi$-orbitals localised on iodide. Near the onset of two spin-orbit thresholds, bright excited states are seen in the experiment and calculations. Excitation of these leads to the formation of slow electrons. The spectroscopy of $\Gamma^-\cdot$CF$_3$ is compared to the well-studied $\Gamma^-\cdot$CH$_3$ cluster, a pre-reaction complex in the text-book $\Gamma^-\cdot$CH$_3$ $S_n2$ reaction. Despite the reversed stereodynamics (i.e. inversion of the C$_3$ axis between $X = H$ and $F$) of the $S_n2$ reaction, striking similarities are seen. Both complexes possess charge transfer excited states near their respective vertical detachment energies and exhibit vibrational structure in their photoelectron spectra. The strong binding is consistent with observations in crossed molecular beam studies and molecular dynamics simulations that suggest that iodine as a leaving group in an $S_n2$ reaction affects the reaction dynamics.

Introduction

Bimolecular nucleophilic substitution ($S_n2$) reactions represent a cornerstone of reactivity in organic chemistry. In its simplest form, the reaction $X^- + CH_3Y \rightarrow XCH_3 + Y^-$ involves the text-book $[X\cdots CH_3\cdots Y]^- \cdots$ activated complex, where $X^-$ attacks CH$_3$ from the backside. The stereodynamics of the reaction are expected from the long-range charge-dipole moment interaction between $X$ and CH$_3$. While in the solution phase, this long-range interaction is screened, the isolated view of the reaction remains mostly valid. As a result, there have been many studies of $S_n2$ reaction dynamics in the gas-phase, which have provided exquisite insight into the reaction mechanisms over many years. While the indirect, backside attack mechanism has been researched in-depth, contemporary experimental and computational studies have explored alternative mechanistic pathways of the $S_n2$ reaction. For example, recent crossed molecular beam studies and atomic/molecular dynamics simulations have shown how the dynamics of the reaction are sensitive to the leaving group, with differing mechanisms contributing when $Y$ is changed. Additionally, photoelectron (PE) spectroscopy of the pre-reaction complex, $X^-\cdot CH_3Y$, can provide much insight about the entrance channel of the reaction, which often plays a deterministic role in the reaction. However, in PE spectroscopy experiments, it has not been possible to control the stereodynamics of the pre-reaction complex and, hence, only the backside attack (direct rebound) mechanism has been probed. In the present study, we make a chemical substitution of the methyl $H$-atoms to $F$-atoms. As the $H$ atoms are mostly indirectly involved in the $S_n2$ reaction, the main reaction coordinate along the $X$–$C$–$Y$ bond is preserved. However, this chemical substitution reverses the stereodynamics of the reactions and allows us to perform PE spectroscopy of the pre-reaction complex for the frontside attack (along the $X$–$Y$–$C$ coordinate).

The gas-phase $S_n2$ reaction has been studied extensively by the groups of Wester and Hase, who have recently observed that the replacement of the leaving group $Y$ from Cl to I in the $S_n2$ reaction, $F^- + CH_3Y$, has dramatic effects on the reaction dynamics. Specifically, for $Y = Cl$, the dominant reaction mechanism is the classic direct rebound mechanism (at energies > 0.6 eV). In contrast, a significant fraction of reactions for the $Y = I$ reaction could be attributed to a direct stripping mechanism, especially at high impact parameters, where the $F^-$ attacks the CH$_3$ and leads to the product ion leaving along the initial direction of the CH$_3$ reactant. Given that the permanent dipole moments of CH$_3$Cl and CH$_3$I are not that different ($\mu = 1.90$ D and $\mu = 1.64$ D, respectively), the change in dynamical orientation of CH$_3$I was assigned to a stronger interaction between the two halogen atoms in the $Y = I$ reaction (the $F^-\cdot$ICF$_3$ complex is bound by 0.97 eV, while $F^-\cdot$ICCH$_3$ is bound by only 0.14 eV). This stronger interaction
changes the orientation at short range leading to differing reaction dynamics.

The most studied pre-reaction $S_n 2$ complex using PE spectroscopy has been $\text{I}^\cdot\cdot\cdot\text{CH}_3$.\textsuperscript{13,22–30} Cyr et al. employed PE, photodetachment and photofragment spectroscopy to characterise the electronic excited states of $\text{I}^\cdot\cdot\cdot\text{CH}_3$, which provided evidence of an intra-cluster charge transfer state with $\text{I}^\cdot$ and $\text{CH}_3$ as the respective donor and acceptor species.\textsuperscript{22,23,25} Although their studies did not indicate that the $S_n 2$ reaction could be photoinitiated, the knowledge gained of the $\text{I}^\cdot\cdot\cdot\text{CH}_3$ complex establishes this system as an ideal test-case to make the H to F substitution and to provide insight into the above-mentioned molecular beam and molecular dynamics simulation studies. We show that, despite the reversed stereochernistry, similarly strong photoabsorption at threshold is observed for $\text{I}^\cdot\cdot\cdot\text{CH}_3$ and $\text{I}^\cdot\cdot\cdot\text{CF}_3$ and many of the spectral features are common to both systems.

It is also noteworthy that $\text{I}^\cdot\cdot\cdot\text{CF}_3$ is potentially an important species in plasma chemistry. Industrially, plasma etching is widely used to fabricate the fine structural components of microelectronic devices.\textsuperscript{31,32} While cations are primarily considered in plasmas, anions are also present and contribute to the chemical cocktail.\textsuperscript{33} The most common process gases for plasma etching include $\text{CF}_4$ and $\text{CF}_3\text{H}$.\textsuperscript{31,32,34} However, these are long-lived global warming gases necessitating their reduced usage.\textsuperscript{35} Alternatives such as $\text{CF}_3\text{J}$, which has a relatively low global-warming potential,\textsuperscript{36–39} have been shown to have similar etching rates to standard mixtures.\textsuperscript{36,40} However, much less is known about the composition of these plasmas.\textsuperscript{41} Dissociative electron attachment to $\text{CF}_3\text{J}$ forms $\text{I}^\cdot$ in high yield,\textsuperscript{42} which may go on to complex to the abundant $\text{CF}_3$ process gas to form species such as $\text{I}^\cdot\cdot\cdot\text{CF}_3$. Hence, these species may be common chemical species in the plasma mix, but have yet to be studied. The present work shows that $\text{I}^\cdot\cdot\cdot\text{ICF}_3$ has a large electron affinity and is strongly bound suggesting that such species may indeed play a role in plasma chemistry.

**Experimental & Computational Details**

A detailed description of the experimental setup will be presented elsewhere and only a brief overview is given here. To generate $\text{I}^\cdot\cdot\cdot\text{ICF}_3$, a $\text{CF}_3\text{J}/\text{Ar}$ mix was expanded through a pulsed Even-Lavie valve into vacuum.\textsuperscript{43} The molecular beam expansion was intersected by an electron beam (300 eV) near the throat of the expansion, generating an electron rich plasma in the high molecular density region. The subsequent expansion and associated cooling provides a snap-shot of the species formed in the plasma.\textsuperscript{44} Anions are extracted from the molecular beam using a linear Wiley-McLaren time of flight spectrometer.\textsuperscript{45} This showed that the dominant species formed were $\text{I}^\cdot$ (which is to be expected from the dissociative electron attachment to $\text{CF}_3\text{J}$) together with $\text{I}^\cdot\cdot\cdot\text{ICF}_3$, formed presumably by the condensation of a $\text{CF}_3$  onto $\text{I}^\cdot$ because of the long-range charge-dipole interaction. We also observed larger clusters with chemical formula $\text{I}^\cdot\cdot\cdot\text{CF}_3\text{J}$. The mass-selected $\text{I}^\cdot\cdot\cdot\text{ICF}_3$ was crossed by nanosecond laser pulses from a Nd:YAG (3$^{rd}$ harmonic) pumped optical parametric oscillator at the focus of the mass-spectrometer. The ejected PEs were accelerated perpendicular to the ion and laser beam axes towards a position-sensitive detector in a velocity-map imaging spectrometer.\textsuperscript{46,47} The focus of the mass-spectrometer was tuned to coincide with the laser/ion interaction point. The PE spectra were reconstructed from the raw images using the polar onion-peeling algorithm.\textsuperscript{48} The electron kinetic energy (eKE) scale was calibrated to the known PE spectrum of $\text{I}^\cdot$. The PE spectrometer had a resolution of $\Delta e\text{KE}/e\text{KE} < 3\%$.

Density functional theory (DFT)\textsuperscript{49} and time-dependent DFT (TDDFT)\textsuperscript{50} calculations were performed to provide a qualitative interpretation of the experimental results and a basic understanding of the electronic structure of $\text{I}^\cdot\cdot\cdot\text{ICF}_3$. For comparative purposes, calculations were also performed on $\text{I}^\cdot\cdot\cdot\text{CH}_3$. It is well known that many approximate exchange-correlation functionals suffer from formal problems for anions (namely positive highest occupied molecular orbital energies), but this can be unproblematic in practical calculations.\textsuperscript{51–56} In the present study, all reported theoretical results were determined using the CAM-B3LYP range-separated exchange-correlation functional,\textsuperscript{57} for which these formal problems are largely overcome.\textsuperscript{58} This functional also contains the relevant physics for describing long-range and charge-transfer excitations, which are relevant to the systems considered.\textsuperscript{59} A further difficulty with describing excited states of anions is that many may be resonances, meaning they must be distinguished from discretized continuum states. We used a standard, basis function exponent-scaling stabilisation approach\textsuperscript{60} to ensure that the excited states reported are appropriate.

The 6-311++G** basis set was used on C, F, and H atoms,\textsuperscript{61–63} while LANL2DZdp was employed in calculations for the I atoms.\textsuperscript{64–66} The calculated ground state optimised geometries were verified to be minima by vibrational analysis and TDDFT calculations were performed at the optimised geometries. We note that our calculations do not include spin-orbit interactions. For iodine, this is of course a major omission – the iodine spin-orbit splitting in the two $^2\text{P}_J$ states of iodine is 0.94 eV and this is not quantitatively reflected in the present calculations. Nevertheless, the calculations provide a useful qualitative basis to assist the interpretation of the experimental results. The Gaussian 09 package has been used throughout.\textsuperscript{67}

**Results**

To determine the ground state geometries, optimisations were performed commencing from frontside and backside (regular $S_n 2$) conformations. The lowest energy structure of $\text{I}^\cdot\cdot\cdot\text{ICF}_3$ has $C_{2v}$ symmetry, with I–I and I–C bond lengths of 3.33 and 2.18 Å, respectively (see Figure 1). In contrast to $\text{I}^\cdot\cdot\cdot\text{CH}_3$, the perfluorinated $\text{I}^\cdot\cdot\cdot\text{ICF}_3$ has the I residing on the side of the iodine, i.e. frontside attack. We have verified that this frontside structure is also obtained when a D3 dispersion\textsuperscript{68} correction is introduced or when MP2 is used.\textsuperscript{69} The change in orientation of $\text{CF}_3\text{J}$ between $X = \text{H}$ and $\text{F}$ correlates with the reversal in permanent dipole moment between $\text{CH}_3\text{J}$ and $\text{CF}_3\text{J}$.
The electropositive H atoms lead to a dipole moment $\mu = 1.78$ D in the direction of the I–C bond, while the strongly electronegative F atoms lead to a dipole moment $\mu = 1.28$ D in the antiparallel direction. The dipole moment vector reversal has the interesting consequence that one can still view I–ICF$_3$ as a reaction precomplex, but with different stereochemistry, and hence, the spectroscopic signatures may be expected to be different between X = H and F.

Figure 2 shows the frequency-resolved (2D) PE spectra collected over the 3.50 $\leq$ $h\nu$ $\leq$ 5.50 eV range with 0.1 eV intervals. 2D PE spectroscopy is a powerful probe of the location and dynamics of anionic resonances, which we have recently applied to radical anions, biomolecules and clusters. Individual PE spectra are plotted in terms of electron binding energy $eBE = h\nu - eKE$ and have been normalised to their maximum intensity. At $h\nu = 3.50$ eV, a narrow peak is visible at $eBE = 3.06$ eV. The profile and position of this peak indicates that it arises from direct photodetachment from atomic I to the neutral iodine $^2P_{3/2}$ ground state. This peak can be clearly identified in the 3.5 $\leq h\nu$ $\leq$ 3.9 eV range, although it is also present at higher photon energies (with much reduced intensity). The appearance of the I$^-$ PE spectrum following the excitation of I--ICF$_3$ implies that two sequential photons were absorbed during the laser pulse (~5 ns).

At $h\nu \geq 5.2$ eV, two broad direct detachment features dominate the PE spectrum. The peaks centred around $eBE = 4.0$ and 4.9 eV have similar spectral shapes and widths. The energy gap between the two features is $\sim 0.9$ eV, which is close to the spin-orbit splitting in the neutral iodine atom (0.94 eV). We assign these two peaks to the direct detachment from I--ICF$_3$, leaving the neutral as $[^2P_{3/2}]$ICF$_3$, and $[^2P_{3/2}]$ICF$_3$ for the high and low $eBE$ peaks, respectively. The vertical detachment energy (VDE) of I--ICF$_3$ corresponds to the maximum of the $[^2P_{3/2}]$ICF$_3$ peak; VDE = 4.03$\pm$0.05 eV (calculated at 4.29 eV). The large spectral width of the peaks (~0.3 eV) and their unresolved vibrational structure could preclude the observation of the 0-0 transition and, thus, also the direct measurement of the adiabatic detachment energy, ADE. Nevertheless, taking the lowest $eBE$ where PE signal becomes apparent from the direct detachment provides a measure of ADE = 3.8$\pm$0.1 eV. This is a blue-shift of >0.7 eV compared to unclustered I$^-$, and much larger than the blue-shift observed in I--CH$_3$L (0.38 eV).
Additionally, present in virtually all PE spectra is a narrow detachment feature peaking at eBE = hv. As an example, this peak is labelled with an asterisk in the $hv = 4.70$ eV PE spectrum in Figure 2; it is also clearly visible in Figure 3. The peak corresponds to the production of PEs with near zero kinetic energy, which is normally associated with an indirect detachment process. Through comparison of the relative intensities of bands present in the PE spectra, the dominant electron loss processes can be identified at each photon energy. With reference to Figure 2, regions labelled as A and B contain PE spectra in which the indirect detachment is the dominant electron loss process occurring. Specifically, at $hv \sim 4.0$ eV and 4.9 eV, the fraction of electrons produced via the direct detachment channels appears at a minimum.

Region A (and B) led to a noticeable increase in total electron signal as a function of $hv$. To explore this further, in Figure 4, a photodetachment (total electron yield) spectrum is presented in the $3.75 \leq hv \leq 4.15$ eV range. Two main peaks can be identified: a broad feature centred at $hv = 3.97$ eV, and a second, less prominent feature centred at $hv = 4.07$ eV. These peaks appear very close to the VDE of the cluster at 4.03 eV (and above the measured ADE = 3.8 eV). For a direct detachment process, a rise in the PE yield is expected when the photon energy passes through threshold, but this is expected to resemble a smooth step function. Here, the observations of peaks in the photodetachment spectrum and the appearance of an indirect process for electron loss (Figure 2, spectral regions A and B), point to a photoexcitation of excited states of the cluster close to the detachment threshold. A similar situation appears to be present at the onset of the second detachment threshold corresponding to the $\Gamma$2P$_{1/2}$ICF$_3$ channel.

Similar to the dominant indirect detachment processes occurring in regions A and B in the 2D PE spectra (Figure 2), the two-photon detachment process at eBE = 3.06 eV is mediated by an electronic excited state. To probe the character of the excited states, DFT and TDDFT calculations were performed.

The relevant molecular orbitals (MOs) of $\Gamma$ICF$_3$ are shown in Figure 5. The highest occupied MO (HOMO) corresponds primarily to the non-bonding atomic p-orbital localised on I and is doubly-degenerate (i.e. the $p_x$ and $p_y$ orbitals – only one of these is shown in Figure 5). The next lowest occupied MO, HOMO–2 corresponds to the $p_z$ orbital on I which interacts with CF$_3$. As a comparison, the analogous MOs for $\Gamma$CH$_3$I are also included in Figure 5. The overall MO structure of $\Gamma$CH$_3$I is very similar to that of $\Gamma$ICF$_3$, despite the reversed stereochemistry. However, it is also clear from the occupied MOs that the charge in $\Gamma$ICF$_3$ is more delocalised onto the CF$_3$ moiety and that $\Gamma$ICF$_3$ has more covalent bonding character than in $\Gamma$CH$_3$I, where the charge is mostly localised on the I atom. The lowest unoccupied MO (LUMO) in $\Gamma$ICF$_3$ and $\Gamma$CH$_3$I are also shown in Figure 5.

Electronic excitation energies and their character were computed using TDDFT and the dominant orbital transitions are included in Figure 5. For $\Gamma$ICF$_3$, the lowest energy transitions were calculated at 4.04 eV and correspond to the HOMO/HOMO–1 → LUMO. These transitions have a low oscillator strength (0.009). Additionally, a very bright transition corresponding to the transition from HOMO–2 → LUMO, with an oscillator strength of 0.91, was identified in the relevant energy range. This bright state has been calculated at 4.82 eV above the anion ground state.

The excited states of $\Gamma$CH$_3$I bear close similarities to those of $\Gamma$ICF$_3$. The lowest energy transitions of $\Gamma$CH$_3$I also corresponds to the degenerate HOMO/HOMO–1 → LUMO excitation. This transition has a similarly low oscillator strength but is red-shifted by 0.27 eV compared to the analogous transition in $\Gamma$ICF$_3$. The analogous HOMO–2 → LUMO bright electronic transition is calculated to lie at 3.88 eV (c.f. 4.82 eV for $\Gamma$ICF$_3$) and has an oscillator strength of 0.33.

Discussion

The experimental VDE of $\Gamma$ICF$_3$ is 4.03 eV, which can be compared to that of the related $\Gamma$CH$_3$I at 3.42 eV, while
that of bare $I^-$ is 3.06 eV.\(^{31}\) The 0.36 eV increase in VDE upon clustering $I^-$ to CH$_3$I has previously been attributed to the attractive interaction between the negative charge and the permanent dipole-moment of CH$_3$I (ignoring any interaction between neutral iodine and CH$_3$I).\(^{28}\) This shift increases to 0.97 eV in $I^-$-ICF$_3$ suggesting a significant degree of covalent bonding between $I^-$ and ICF$_3$. This covalent bonding is apparent from the MOs shown in Figure 5 and the molecular structure in Figure 1 that indicate some $I_2^-$-CF$_3$ character to the cluster. The calculated $I$-$I$ distance in the complex is very similar to that of $I_2^-$ (3.33 Å compared to 3.32 Å calculated at the same level of theory) and also show that the C-$I$ bond in the complex (2.18 Å) is slightly elongated in comparison to CF$_3$I (2.14 Å). Hence, these observations suggest there is some $I_2^-$ character and weakening of the bonding interaction across the C-$I$ bond. The covalent nature is also consistent with the increased spectral width of the PE peaks (~300 meV) compared to those observed in $I^-$-CH$_3$I, which are on the order of 25 meV. The fact that the spectral shape for direct detachment is mostly Gaussian suggests that the final neutral state has a very different geometry to that of the anion.

Despite the apparent covalent character of the bonding in $I^-$-ICF$_3$, it also retains much non-covalent character and has many similarities to $I^-$-CH$_3$I. The degenerate lowest energy transitions are from the relatively non-binding p orbitals localised on $I^-$. While this transition carries a very small oscillator strength, its presence is consistent with the PE spectra at $hv < 3.9$ eV in Figure 2. Specifically, photodetachment from $I^-$ can be seen by the narrow PE peak at eBE = 3.06 eV, which presumably comes about from excitation of $I^-$-ICF$_3$ via the bound low-energy excited states that leads to dissociation of the cluster forming $I^-$. This atomic fragment can subsequently be photodetached in the presence of the laser field which remains present for ~ 5 ns (FWHM). The PE signal in this range was very small, consistent with the low oscillator strengths of the HOMO/HOMO−1 → LUMO transition and with the 2 sequential photon process.

For $hv \geq 3.80$ eV, the total PE signal increases sharply. The total PE signal shown in Figure 4 has a peak at 3.97 eV. Concomitant to the increase in total PE yield is a change in the appearance of the PE spectrum: the detachment from $I^-$ becomes a very minor channel while most signal appears at very low kinetic energy. This indirect detachment channel indicates that an intermediate excited state is accessed. Given the large increase in PE yield (Figure 4), we assign this to the calculated bright electronic transition (HOMO−2 → LUMO). As our calculations do not include spin-orbit coupling, the calculated transition energy is some way off. We do, of course, expect a spin-orbit component and this is clearly seen in Figure 2 as a second indirect channel opens up at $hv \sim 4.9$ eV (B in Figure 2).

At $hv = 4.00$ eV, there is a direct detachment peak from $I^-$-ICF$_3$ and this peak remains present for $hv \geq 4.00$ eV. We conclude that the bright state is very close to threshold. It is approximately 60 meV below the VDE. This also suggests that the total PE yield shown in Figure 4 is a convolution of the electron loss via the indirect channel and the direct detachment channel. Despite this complication, the second maximum observed at 4.07 eV does not correlate with this onset and appears to be an additional peak in the excitation cross section – i.e. a vibrational level of the excited state. The spacing of ~100 meV is very similar to that observed in the PE spectra (see Figure 3).

The observation of an excited state near threshold (for both spin-orbit channels) with vibrational structure is similar to observations in $I^-$-CH$_3$I. In that case, vibrational progressions at 68 meV were observed in both the PE spectra and the photofragment action spectra monitoring $I^-$ loss or electron loss. This vibrational progression was assigned to the $v_3$ mode (based on the 66 meV frequency for the IR active $v_4$ mode in CH$_3$I) and predominantly involves the C-I stretch. In their assessment of the $I^-$-CH$_3$I spectroscopy, Johnson and coworkers concluded that the vibrational structure in the PE spectra comes about from non-Franck-Condon (vibrionic) effects.\(^{28}\) The non-Franck-Condon behaviour was further supported by the fact that the vibrational activity seen in their PE spectra showed a dependence on the eKE of the outgoing electrons.\(^{28}\)

Vibrational structure is also observed here in $I^-$-ICF$_3$ and the vibrations appear more resolved at $hv = 4.2$ and 5.1 eV (see Figures 2 and 3), where the two spin-orbit thresholds open. In the case of CF$_3$I, the IR spectrum is dominated by the $v_1$ and $v_2$ mode (92 and 134 meV, respectively) of $a_1$ symmetry, which correspond to the symmetric CF$_3$ stretch and a C-I stretch (that also involves the CF$_3$ umbrella mode; this mode is similar to the $v_5$ mode in CH$_3$I), respectively. Both these modes are close to the observed ~100 meV spacing in the PE spectrum (Figure 3) and the electron yield spectrum (Figure 4).
Cyr et al. probed the spectroscopy of $\Gamma \cdots \text{CH}_3I$ using electron yield as well as fragmentation action spectra with the two products being $\Gamma^+$ and I$_2^-$. However, the main product is electron loss. In their PE spectra, no slow electrons were observed. This may be because of the low collection efficiency at low eKE in their experiment. Here, we clearly show for $\Gamma \cdots \text{ICF}_3$ that the electrons are lost with a very low eKE. The mechanism ascribed by Johnson and co-workers for the dynamics is one in which the fragmentation can be viewed as an electron-molecule scattering process, leading to dissociation that is mediated by the $\sigma^*$ orbital along the C–I bond. This conclusion is consistent with the excited state calculated in Figure 5, where such a $\sigma^*$ character is clearly present. In the present case of $\Gamma \cdots \text{ICF}_3$, many analogies can be drawn. By inspection of the MO diagram in Figure 5, a similar $\sigma^*$ orbital is excited and an analogous vibrational progression involving the C–I stretch is seen in the PE spectra and photodetachment spectra of $\Gamma \cdots \text{ICF}_3$. Here, we have not been able to monitor atomic or molecular fragments directly and have only observed the electron loss channel. Nevertheless, it would appear that a similar overall mechanism can be ascribed here for $\Gamma \cdots \text{ICF}_3$. The fact that the indirect electrons appear at very low eKE, regardless of the photon energy may arise because the electrons are lost along the dissociative coordinate. It would clearly be of interest to perform fragment (probing $\Gamma^+$ and I$_2^+$) action spectra, but these experiments are not possible in our current arrangement.

While the electronic structure of the Sn2 pre-reaction complexes appears little affected, clearly the stereochemistry has inverted. Therefore, $\Gamma \cdots \text{ICF}_3$ effectively serves as a probe for frontside attack entrance channel complex. As described in the introduction, recent crossed molecular beam experiments and simulations have shown that for the reactions $F^+ + \text{CH}_3I$, a change of Y = Cl to I led to an enhanced frontside attack, even though the long-range interactions is similar. Hence, it was suggested that a stronger interaction between $F^+$ and I compared to $F^+$ and CI was responsible. In the present study, we have effectively trapped a frontside attack pre-reaction complex (with $\Gamma$ as a reactant) and indeed, a significant covalent bonding character is observed. The binding energy can be roughly estimated from the increase in the VDE of the cluster relative to that of bare iodide. In the $\Gamma \cdots \text{CH}_3I$, this is 0.36 eV compared to 0.97 eV for $\Gamma \cdots \text{ICF}_3$. The former is a purely electron-dipole moment interaction and, assuming that the magnitude of the permanent dipole of CH$_3$I and CF$_3$I are similar, then the covalent contribution to the binding is approximately the difference in binding energy of $\Gamma \cdots \text{CH}_3I$ and $\Gamma \cdots \text{ICF}_3$, or ~0.6 eV. Although this is a very rough estimate, it does suggest that the covalent character is stronger than the overall repulsive charge-dipole moment interaction in $\Gamma \cdots \text{ICH}_3$ (0.36 eV). It would be of interest to study the $F^+ \cdots \text{CH}_3I$ complex as a more direct comparison to the reaction dynamics studies, where a well depth of 0.97 eV was calculated for $F^+ \cdots \text{ICH}_3$. Overall, given the growing evidence of the existence and contributions of mechanisms other the traditional backside attack for Sn2 reactions, the development of new experimental probes for complexes along such reaction coordinates should prove to be useful in determining energetics and structures of intermediates.

**Conclusion**

A photoelectron (PE) and photodetachment spectroscopic study of the $\Gamma \cdots \text{ICF}_3$ complex is presented, supported by DFT and TDDFT calculations. The binding in the cluster can be viewed as a combination between a non-covalent charge-dipole interaction and a covalent contribution along the I–I–C bond. The PE spectra show direct detachment channels, leaving the neutral in either spin-orbit states of the anion. The lowest (measured) detachment energy is 4.03 eV and the adiabatic energy is approximately 3.8 eV. Near both thresholds, there is clear evidence of excitation to an excited state, which is corroborated by the PE yield spectrum around the first threshold. Electronic structure calculations show that this excited state can be assigned to a transition with charge-transfer character from the iodide to the ICF$_3$ moiety.

The spectroscopy is compared to the much-studied $\Gamma \cdots \text{CH}_3I$ cluster, which is the pre-reaction complex of the corresponding Sn2 reaction. The electronic structure of $\Gamma \cdots \text{ICF}_3$ shows many parallels, even though the geometric structure is very different because of the reversal of the dipole moment between CH$_3$I and CF$_3$I (i.e. the pre-reaction complex stereoenergetics have been reversed). Specifically, both possess an excited state very close to threshold and show evidence of vibrational structure in the PE and photodetachment spectra. We assign the spectroscopy and excited state dynamics along parallel lines to that of $\Gamma \cdots \text{CH}_3I$: the excited state near threshold can be viewed as an electron scattering state that is strongly coupled to the $\sigma^*$ orbital on the I–C bond, leading to photoemission and dissociation (which was not measured here). We conclude that the overall electronic excited state structure is insensitive to the stereodynamics of the Sn2 pre-reaction complex.

Chemical dynamics simulations and crossed-beam imaging studies have recently shown that, for the $F^+ + \text{CH}_3I$ reaction, the reaction is influenced by short-range attraction and often attacks as $F^+ + \text{IC}_3H$, implying that the covalent interaction of the pre-reaction complex is larger than the long-range electron-dipole interaction. The relatively strong covalent bonding observed between the two iodine atoms here may also be sufficient to overcome the repulsive electron-dipole moment interaction leading to an attractive well in the frontside attack of the $\Gamma$ + CH$_3$I Sn2 reaction. However, this well is weaker than the normal backside orientation as shown by the PE spectroscopy of Johnson and coworkers. In general, the replacement of H atoms with F atoms may serve as a useful general tool to invert the stereodynamics of Sn2 pre-reaction complexes, probe their interactions, and serve as a method for investigating non-traditional Sn2 reaction mechanisms.
