13

14 Palaeomagnetic techniques for estimating the emplacement temperatures of volcanic

15 deposits have been applied to pyroclastic and volcaniclastic deposits in kimberlite pipes in

16 southern Africa. Lithic clasts were sampled from a variety of lithofacies from three pipes

17 for which the internal geology is well constrained (the Cretaceous A/K1 pipe, Orapa Mine,

18 Botswana, and the Cambrian K1 and K2 pipes, Venetia Mine, South Africa). The sampled

19 deposits included massive and layered vent-filling breccias with varying abundances of

20 lithic inclusions, layered crater-filling pyroclastic deposits, talus breccias and volcaniclastic

21 breccias. Basalt lithic clasts in the layered and massive vent-filling pyroclastic deposits in

22 the A/K1 pipe at Orapa were emplaced at >570°C, at 200–440°C in the pyroclastic crater-

23 filling deposits, and at <180°C in crater-filling talus breccias and volcaniclastic breccias.

24 The results from K1 and K2 pipes at Venetia are suggestive of emplacement temperature

25 estimates for the vent-filling breccias of 260°C to >560°C, although interpretation of these

26 results is hampered by the presence of Mesozoic magnetic overprints. These temperatures

27 are comparable to the estimated emplacement temperatures of other kimberlite deposits and

28 fall within the proposed stability field for common interstitial matrix mineral assemblages

29 within vent-filling volcaniclastic kimberlites. The temperatures are also comparable to

30 those obtained for pyroclastic deposits in other silicic volcanic systems. Because the lithic

31 content of the studied deposits is 10–30%, the initial bulk temperature of the pyroclastic

32 mixture of cold lithic clasts and juvenile kimberlite magma could have been 300–400°C

33 hotter than the palaeomagnetic estimates. Together with the discovery of welding and

34 agglutination of juvenile pyroclasts in some pyroclastic kimberlites, the palaeomagnetic

35 results indicate that there are examples of kimberlites where phreatomagmatism did not

36 play a major role in the generation of the pyroclastic deposits. This study indicates that

37 palaeomagnetic methods can successfully distinguish differences in the emplacement

38 temperatures of different kimberlite facies.

Introduction

Kimberlites are mantle-derived ultramafic volcanic rocks preserved in dykes, volcanic pipes and craters (Dawson, 1971; Mitchell, 1986). Over 5000 kimberlite occurrences are known (Kjarsgaard, 1996), but are confined to the ancient cratonic regions of continents (e.g., south, central and western Africa; Canada, Australia, Russia). Their emplacement ages vary from early Proterozoic through to early Tertiary and because no kimberlite eruptions have ever been witnessed many aspects of kimberlite volcanism are unclear (Sparks et al, 2006). In addition, kimberlite rocks are usually highly altered, particularly the matrix – though less so for incorporated lithic clasts, and contaminated with mantle and crustal debris (Mitchell, 1986; Sparks et al., 2006; Stripp et al., 2006; Buse et al., 2010). This has made it difficult to reconstruct the fundamental properties of the magma, such as its chemistry, temperature, viscosity and volatile content (e.g., Sparks et al., 2006).

Two principal theories have been put forward as the driving force for kimberlite eruptions: (1) the exsolution of magmatic volatiles (e.g., Dawson, 1971; Clement and Reid, 1989; Field and Scott Smith, 1999; Sparks et al., 2006; Wilson and Head, 2007), and (2) the interaction of rising kimberlite magma with ground water (e.g., maar-diatreme model of Lorenz, 1975; Kurszlaukis et al., 1998; Lorenz and Kurszlaukis, 2007). Recent dynamical models propose a volatile-driven eruption mechanism similar to other types of explosive volcanic eruptions (see Sparks et al., 2006), and the similarities between steep-sided kimberlite pipes and maars and diatremes, formed during hydrovolcanic explosions, are striking. As in other varieties of volcanism the two models are not mutually exclusive.

70

71 The ability to estimate the emplacement temperatures of pyroclastic deposits using

72 palaeomagnetic methods has proved useful in distinguishing between magmatic and

73 phreatomagmatic modes of eruption, and in discriminating between pyroclastic deposits

74 and epiclastic deposits (Aramaki and Akimoto, 1957; Wright, 1978; Hoblitt and Kellogg,

75 1979; Downey and Tarling, 1991; Bardot et al., 1996). The technique, pioneered by

76 Aramaki and Arimoto (1957), has been successfully applied to many deposits around the

77 world (Kent et al., 1981; Hoblitt and Kellogg, 1979; Clement et al., 1993; Mandeville et al.,

78 1994; De'Gennaro et al., 1996; Cioni et al., 2004; McClelland et al., 2004; Porreca et al.,

79 2008; Paterson et al., 2010). Palaeomagnetic emplacement temperature determinations of

80 pyroclastic deposits have also been shown, in certain cases, to be as accurate as direct

81 measurements taken shortly after eruption (e.g., the 1980 eruption of Mt. St. Helens;

82 Paterson et al., 2010).

83

84 Several attempts have been made to estimate the emplacement temperatures of kimberlite

85 deposits. The general absence of thermal metamorphic effects on entrained xenoliths and

86 in adjacent country rocks has led some authors to propose emplacement temperatures of

87 <500°C for volcaniclastic kimberlite deposits (e.g., Watson, 1967; Mitchell, 1986; Skinner

88 and Marsh, 2004). Sosman (1938) deduced intrusion temperatures of 340°C for North

89 American kimberlites from thermal effects on coal inclusions (see Watson, 1967). Stasiuk

90 et al. (1999) used reflectance values in dispersed organic matter inclusions within Canadian

91 kimberlites to deduce temperatures of 150–200°C for pipe-facies and <100°C for crater-

92 facies volcaniclastic kimberlites. Palaeomagnetic studies by McFadden (1977) on wall

93 rock samples and accidental inclusions close to the contacts of four South African pipes

94 suggested emplacement temperatures of ~300°C. The stability fields of the common

95 alteration assemblages in kimberlite pyroclastic rocks give minimum temperatures of 250–

96 400°C (Stripp et al., 2006; Buse et al., 2010).

97

98 Here we present the results of palaeomagnetic measurements of the emplacement

99 temperatures of a range of pyroclastic and volcaniclastic kimberlite deposits within three

100 contrasting kimberlite pipes in southern Africa, for which the internal geology is well

101 constrained by recent geological studies (Field et al., 1997; Brown et al., 2009; Gernon et

102 al., 2009a). Measurements of the thermoremanent magnetization (TRM) of included lithic

103 clasts show that the range of emplacement temperatures varies from around ambient for

104 volcaniclastic deposits, interpreted as talus breccias and debris flow deposits, through to

105 >200 to >570°C for pyroclastic deposits – temperatures which are similar to those obtained

106 for pyroclastic deposits in other volcanic systems. We discuss the implications of these

107 results in the context of the supporting geological evidence for the mode of formation of the

108 kimberlite deposits and for the nature of kimberlite eruptions.

109

110 **Geological setting**

111

112 Orapa A/K1 kimberlite pipe, Botswana

113

114 The Orapa A/K1 kimberlite (Fig. 1a and 2a) comprises two steep-sided coalescing pipes

115 (north and south) that were intruded at ~92.1 Ma through Archaean basement (granite-

116 gneisses and tonalites) and Phanerozoic sediments and basalt lavas of the Karoo

117 Supergroup (Field and Scott-Smith, 1999). The geology of the Orapa A/K1 pipe is

118 described by Field et al. (1997) and Gernon et al. (2009a). The upper portions are

119 dominated by a layered pyroclastic kimberlite lithofacies (Northern Pyroclastic Kimberlite,

120 NPK; Fig. 1a) which is characterised by abundant basement and basalt fragments (≤10 m

121 diameter). These fragments can be concentrated in crude, reverse- to normally graded

122 layers. The matrix comprises abundant serpentinised olivine macrocrysts and phenocrysts

123 and juvenile lapilli. Interstitial pore-space is filled with serpentine-diopside cement. At

124 depth the layering disappears and the deposit becomes massive (Field et al., 1997).

125

126 The south pipe is larger than the north pipe and its crater cuts the north pipe (Field et al.,

127 1997). Talus deposits outcrop along the western margin of the south pipe and comprise

128 crudely bedded clast-supported basalt breccias and bedded crystal-rich grain flow deposits

129 (Fig. 1a and 2a), both of which dip towards the centre of the pipe at the angle of repose

130 (Field et al., 1997). Field et al. (1997) propose that these deposits formed by the post-

131 eruption decrepitation of the pipe walls and a surrounding tephra cone. Inner crater

132 lithofacies (Southern Volcaniclastic Kimberlite, SVK; Fig. 1a and 2a) comprise a sub-

133 horizontally layered sequence of poorly sorted basalt-bearing lapilli-tuffs and breccias and

134 stratified olivine tuffs and grits. These are interpreted as a series of ignimbrites derived

135 from neighbouring pipes and sheet-flood deposits (Gernon et al., 2009a).

136

137 K2 and K1 pipe, Venetia Mine, South Africa

138

6

139   The Venetia kimberlite cluster is located in the Limpopo region of South Africa (Fig. 1b).

140   It comprises 14 pipes outcropping over ~4 km^2 (Seggie et al., 1998; Kurszlaukis and

141   Barnett, 2003). The pipes were intruded at ~519 Ma into complex Proterozoic basement

142   comprising biotite gneiss, biotite schists and amphibolite gneiss, quartzo-feldspathic gneiss

143   and metasediments (Phillips et al., 1999). Shale and lava clasts within the pipes indicate

144   that Waterberg Formation rocks covered the basement at time of emplacement (Kurszlaukis

145   and Barnett, 2003).

146

147   K2 is a steep-sided volcanic pipe which tapers at depth (Kurszlaukis and Barnett, 2003;

148   Brown et al., 2009). It is 250 m by 300 m wide and is broadly divisible into two parts (Fig.

149   1b and 2b). K2 East is dominated by massive volcaniclastic kimberlite (MVK). K2 West

150   is filled with crudely bedded coarse-grained country rock breccias (Br) and matrix- or clast-

151   supported volcaniclastic kimberlite breccias (mVKBr, cVKBr) with variable amounts of

152   lithic lapilli, blocks and boulders. The contact between these two halves is marked by a

153   shear surface dipping ~64° westwards (Fig. 1b and 2b). The breccias in K2 are thought to

154   result from two competing processes: (1) gravitational collapse of pipe margins that

155   generated abundant brecciated country rock (Br lithofacies) and (2) proximal fallout of

156   country rock clasts and pyroclasts from eruption jets during explosive eruptions (VKBr

157   lithofacies; Brown et al., 2009). The breccias pre-date the MVK in K2 East, which

158   represents the deposits of a later stage of explosivity in the pipe (Kurszlaukis and Barnett,

159   2003; Brown et al., 2009). K1 is an irregular-shaped kimberlite pipe that is mainly filled

160   with MVK similar to that found in K2 (Fig. 1c and 2c; Kurszlaukis and Barnett, 2003;

161   Walters et al., 2006).

162

Palaeomagnetic determination of emplacement temperatures

164

165   Palaeomagnetic determination of the emplacement temperatures of volcanic deposits relies

166   on the fact that lithic clasts incorporated into a pyroclastic (or volcaniclastic) deposit will

167   have originally been magnetized *in situ* prior to eruption and will thus possess a natural

168   remanent magnetization (NRM) aligned with the Earth's magnetic field during their

169   formation or during some metamorphic event. The nature of this pre-eruption

170   magnetization is not critical to the interpretation. During the eruption these clasts are

171   thrown into the air and 'jumbled up' such that the direction of magnetization will now vary

172   from clast to clast when they come to rest. If the deposits are emplaced above ambient

173   temperatures, the lithic clasts are heated during their incorporation into the deposit and will

174   cool to ambient temperature in their present position. If the clast contains a population of

175   magnetic grains with a spectrum of grain sizes, a portion of the original magnetization with

176   unblocking temperatures (T_{ub}) less than or equal to the emplacement temperature (T_e) will

177   be reset by this heating and replaced or overprinted by a new partial thermoremanent

178   magnetization (pTRM). Thus, the clasts will now contain two components of

179   magnetization – a low unblocking temperature component that will be parallel to the

180   Earth's magnetic field at the time of cooling, and the original high unblocking temperature

181   magnetization that will have random orientations from clast to clast. The emplacement

182   temperature (T_e) of the lithic clasts can, therefore, be determined by progressive thermal

183   demagnetization of the components of magnetization present within the clast. The estimate

184   of T_e is the temperature above which the overprinted magnetization is removed and the

8

185   randomized high temperature magnetization is uncovered (e.g., McClelland and Druitt,

186   1989; Bardot, 2000).

187

188   Emplacement temperature validation

189

190   The palaeomagnetic technique may give erroneous results if the magnetic mineralogy of a

191   lithic clast has altered by being heated, either during the eruption or during the laboratory

192   experiment. Alteration of the ferromagnetic mineralogy of a lithic clast may also have

193   occurred post-eruption during hydrothermal alteration of the deposits, and by low

194   temperature diagenesis and weathering. The growth of a new magnetic phase during the

195   eruption or during later alteration or laboratory heating could produce a chemical remanent

196   magnetization (CRM) which would parallel the Earth's magnetic field at the time of

197   alteration and may partly or completely replace the existing magnetization (Bardot and

198   McClelland, 2000). The low unblocking temperature component in some samples could

199   therefore have two origins; thermal activation (pTRM), which cannot exceed the T_e, or a

200   CRM retained in newly formed or chemically altered grains resulting from alteration

201   events. A secondary CRM may not demagnetize in the laboratory until the Curie

202   temperature of the new magnetic phase, and this temperature would not be related to the

203   emplacement temperature of the deposit (McClelland et al., 2004). In order to test the

204   reliability of the emplacement temperature estimates, we monitored the variation of

205   magnetic susceptibility with temperature to determine the Curie temperature (T_c) of the

206   magnetic-mineral assemblages in the lithic clasts. To determine if the ferromagnetic

207 mineralogy of the lithic clasts was altered during syn- or post-eruption processes, the

208 mineralogy of lithic clasts was compared with corresponding country rock samples.

209

210 An additional complication arises from the possible presence of Viscous Remanent

211 Magnetisations (VRM). This is the magnetization that is gradually acquired by very small

212 magnetic grains with very short relaxation times – they tend to rapidly realign with the

213 most recent magnetic field, and yield a low-temperature component of magnetization that

214 parallels the most recent field and can mask older components of magnetization. A VRM

215 can be removed by thermal demagnetization at a specific time-temperature combination

216 related to that at which the rock acquired the VRM. In essence this means that if the rock

217 acquired a VRM over a period of 780,000 years (the time since the last magnetic reversal)

218 we would need to heat it to a substantially higher temperature on a laboratory time scale (50

219 minutes) to remove it.   This means that there is a lower limit on the emplacement

220 temperature that we can determine using the palaeomagnetic technique, and for rocks older

221 than 780,000 years this has been determined empirically to be 163°C (Bardot and

222 McClelland, 2000). We have chosen to be conservative, given that there will also be some

223 error on the temperature settings in our furnace (±10°C), and have not attributed any

224 geological significance to components fitted below 180°C.

225

226 **Methods**

227

228 Sampling strategy

229

10

230   The sampling of the lithic clasts followed that outlined by McClelland and Druitt (1989)

231   and Bardot (2000). Given that the clasts were irregularly shaped, rigid plastic plates were

232   glued onto the surface of *in-situ* clasts and the strike and dip of the plate was recorded.

233   This was done so that we would have a perfectly flat surface for precisely orienting the

234   clasts. Clasts ranged in size from 4 to 24 cm diameter. Cores with a diameter of 1.9 cm

235   were drilled from Orapa A/K1 basalt clasts. Standard 2.5 cm diameter cores were drilled

236   from Venetia K1 and K2 clasts because they possessed weaker NRMs. Multiple core

237   specimens were obtained from individual lithic clasts to detect any magnetic

238   inhomogeneity or thermal gradients within the samples.

239

240   In the Orapa A/K1 pipe 110 basalt lithic clasts were sampled from the north pipe (NPK)

241   and the south pipe (SVK and talus breccias; Fig. 1a and 2a). Fifty five basalt lithic clasts

242   were sampled from the NPK from two localities at depths of 155 m and 140 m below

243   present surface (Sites 1 and 2 respectively; Fig. 1a and 2a). Five clasts were sampled from

244   talus breccias (Site 3; 95 m below present surface (bps)). Eight clasts were sampled from

245   inner crater SVK deposits at Site 4 (110 m bps) and 42 clasts from Site 5 (140 m bps). All

246   samples are tholeiitic Stormberg Formation basalt of Jurassic age. They are generally fine-

247   to medium-grained, holocrystalline and feldspar-phyric, with a seriate groundmass of

248   feldspars and pyroxenes. The feldspars exhibit embayed grain boundaries and breakdown

249   to oxides and the groundmass is altered to clay and chlorite.

250

251   Thirty-five lithic clasts were collected from the K1 and K2 pipes, Venetia mine. Thirty-

252   three clasts were collected from the two main lithofacies in K2: 28 from the matrix-

253   supported volcaniclastic kimberlite breccias (mVKBr) in K2 West and 5 from the massive

254   volcaniclastic kimberlite deposits (MVK) in K2 East (Fig. 1b and 2b). Because the

255   incorporation of lithic clasts can significantly cool pyroclastic mixtures (Marti et al., 1991)

256   only localities with <35 vol.% lithic clasts were chosen for sampling. Sampling localities

257   (Fig. 1b) aimed to provide a good radial and azimuthal spread, collecting six to eight clasts

258   from a site spread over 5 to 10 m of outcrop. Sites 1 to 8 are exposed at 90 m bps, and sites

259   9 and 10 at 75 m bps (Fig. 1b). Two clasts were collected from MVK deposits in K1 (Site

260   1; Fig. 1c) at a depth of 170 m below present surface. Amphibolite gneiss clasts (13 clasts)

261   were preferentially taken because they are the most likely to carry a strong and stable

262   magnetization due to a suitable ferromagnetic mineral content and a competent massive

263   structure. At some localities amphibolite clasts were scarce and biotite gneiss (5 clasts) and

264   garnetiferous biotite schist (5 clasts) were sampled instead. Three argillite clasts, two

265   basalt clasts, and seven clasts of Proterozoic dolerite were also sampled. At sites 6 and 7

266   there were no clasts that could be sampled.

267

268   **Laboratory methods**

269

270   Measurements of the natural remanent magnetization (NRM) were made in a magnetically

271   shielded laboratory using a 2-G Enterprises cryogenic magnetometer. The samples were

272   demagnetized using a Magnetic Measurements thermal demagnetizer with a residual field

273   less than 50 nT in heating steps of 20°C or 40°C until the remaining intensity was less than

274   5% of the NRM. Occasionally more detailed steps were used where demagnetization

275   occurred in a narrower temperature window. Demagnetization results were visually

276 inspected using orthogonal vector component plots (Zijderveld, 1967) and stereographic

277 projections. Remanence directions were determined from stable end-points using principal

278 component analysis (Kirschvink, 1980). Magnetic components were considered stable

279 where they were defined by at least three points on vector component diagrams and had a

280 maximum angular deviation (MAD) not exceeding 15°. Statistical analysis of the

281 magnetization components and directional data were evaluated using Fisher (1953)

282 spherical statistical parameters. The significance of groupings of vector components from

283 each site was assessed using Watson's (1956) test for randomness.

284

285 The Curie temperature T_c of representative samples was determined by taking

286 measurements of low-field susceptibility versus temperature, using a Agico KLY-2

287 Kappabridge magnetic susceptibility meter with furnace attachment, on 1–2 cm^3 of

288 powdered sample taken from lithic clasts prior to thermal demagnetization. Measurements

289 of susceptibility were made every 15–20 s as the sample was heated from 40–700°C, and

290 then as it cooled back to 40°C, with a typical heating-cooling cycle taking about 2 hours.

291 The Curie temperatures were determined using the inverse-susceptibility method of

292 Petrovský and Kapička (2006). Polished sections were analysed using back-scattered

293 imagery on a JEOL JSM-840A scanning electron microscope (SEM) and energy dispersive

294 X-ray spectroscopy (EDS) using an Oxford Instruments ISIS 300 system.

295

296 **Results**

297

298 Orapa A/K1 kimberlite pipe, Botswana

13

299

300   The 110 basalt samples displayed NRM intensities from 0.20 to 48.7 amperes/meter (A/m).

301   North pipe (NPK) samples displayed the highest intensities (1.05 to 48.7 A/m); with the

302   majority displaying intensities >20 A/m. The lowest NRM intensities are displayed by

303   talus breccia samples (<1 A/m). Fifty six samples were fully demagnetized after the 590°C

304   heating step with the remaining samples demagnetized over heating steps between 600 and

305   700°C, indicating that the samples contain ferromagnetic grains with T_c >590°C. All

306   samples exhibited stable behaviour during thermal demagnetization and displayed well-

307   defined (MAD<15°) single or two-component magnetizations. Homogeneous thermal

308   demagnetization behaviour is displayed between samples taken from the same clast in all

309   but three clasts – where different emplacement temperature estimates were obtained from

310   the rim and interior of the clasts.

311

312   Thermal demagnetization behaviour

313

314   Representative thermal demagnetization data for north pipe (NPK) and south pipe (SVK

315   and talus breccias) samples are shown in Fig. 3. Groupings of magnetization directions on

316   equal-area stereonets are shown in Fig. 4; statistical parameters are detailed in Table 1.

317   Well-defined emplacement temperature determinations are obtained from clasts where two

318   components of magnetization are identified through thermal demagnetization. In clasts

319   where the primary magnetization has been overprinted by thermal activation (pTRM) of the

320   magnetism, the two components are separated by a change in the direction of the

321   magnetization, which occurs at the emplacement temperature. This behaviour is depicted

322   in Figs. 3a and 3b for samples AK1-38a1 and AK1-51a1 respectively (SVK; Site 5). In

323   sample AK1-38a1 (Fig. 3a) the initial magnetic vector points northwest (D = 330.5°) and

324   upwards (I = -60.6°). As demagnetization progresses (up to 240°C) the declination of the

325   vector rotates westwards and the inclination steepens. At subsequent heating steps the

326   direction of the vector remains similar, but the intensity decreases until the sample is fully

327   demagnetized between 570 and 590°C. These changes in the magnetization vector are

328   mapped by two separate lines. All points between room temperature and 240°C can be

329   fitted by a well-defined line (MAD = 2.9°) with a direction (D = 342.3°, I = -54.9°) that is

330   similar to the Cretaceous Earth's field direction (D = 350°, I = - 69°) for the region

331   (Hargreaves and Onstott, 1980). The points from 280°C to the origin of the plot lie on a

332   high-temperature line (MAD = 10.0°) with a direction (D = 245.1°, I = -65.9°) that is

333   different to that of the low-temperature component and the Cretaceous Earth's field

334   direction. This line represents the original magnetization of the clast which has moved to a

335   different orientation during transport in the deposit. An emplacement temperature (T_e)

336   estimate uses the temperature range between the last point on the low-temperature line and

337   the first point on the high-temperature line, in this case T_e = 240–280°C. In another

338   example AK1-51a1 (Fig. 3b) all points from room temperature to 360°C lie on a low-

339   temperature line with a direction (D = 359.6°, I = -32°) that is similar to the Cretaceous

340   direction, and all points from 400°C to the origin lie on a line with a direction (D = 291.7°,

341   I = -17.4°). In this case the emplacement temperature estimate is 360–400°C. We define

342   this demagnetization behaviour as 'type-1'. Three clasts display a variation in T_e estimates

343   between specimen cores taken from the interior and exterior of the clast. Sample AK1-

344   25a1 (Fig. 3c) taken from the exterior of the clast displays a two-component magnetization

345   with the separation of the two-components occurring at T_e = 280–320°C. In sample AK1-

346   25a2 (Fig. 3d) taken from the interior of the clast only a single component is present which

347   is identical to the high-temperature component of the exterior sample. This is the original

348   magnetization of the clast and indicates the core has not been heated above the minimum

349   temperature which can measured by palaeomagnetic methods.

350

351   If lithic clasts are heated to temperatures greater than the maximum Curie temperatures (T_c)

352   of the minerals they contain, the original magnetization will be completed overprinted by a

353   new pTRM component, and the magnetization will be a single-component parallel to the

354   Earth's magnetic field. In these examples the maximum T_c of the minerals will provide

355   minimum emplacement temperature estimates. This is defined as 'type-2' behaviour and

356   two examples with different maximum T_c are shown in Fig. 3e, f. Sample AK1-76b2 (Fig.

357   3e) is fully demagnetized between 660°C and 680°C and a single component of

358   magnetization (D = 1.9°, I = -67.4°) is defined by a well-fitted line (MAD = 4.5°) through

359   all data points from room temperature to the origin. The single-component (D = 337.2°, I =

360   -71.4°) in sample AK1-101a2 (Fig. 3f) is fully demagnetized between 570 and 590°C.

361   Both directions are similar to the Cretaceous Earth's field direction and the samples provide

362   minimum T_e estimates of >660°C and >570°C respectively. Samples where the natural

363   magnetic grain size distribution is extremely restricted and no grains with low unblocking

364   temperatures (T_{ub}) are present are defined as 'type-3' behaviour. No thermal overprint

365   would be recorded in these clasts if heated to temperatures less than the minimum T_{ub}. In

366   sample AK1-2a2 (Fig. 3g) no demagnetization occurs in heating steps up to 360°C, after

367   which the magnetization is removed between 400 and 590°C. Similar behaviour is shown

368   by sample AK1-5a1 (Fig. 3h) where demagnetization only occurs between 440 and 620°C.

369   The magnetizations have a random direction and indicate the clasts have been emplaced at

370   temperatures less than the minimum T_{ub}. The samples therefore provide maximum T_e

371   estimates of <400°C and <440°C respectively.

372

373   All 110 basalt lithic clasts displayed well-defined single or two-component magnetizations

374   of one of the three demagnetization behaviour types (types 1, 2 or 3). Twenty-five samples

375   display a two-component magnetization (type-1) delineated by sharp changes in the

376   direction of the magnetization vectors. Statistical grouping of the low-temperature

377   components in these clasts is only observed for Site 5 (SVK; n = 23) with a mean direction

378   (D = 330°, I = -43.9°, α95 = 12.2; Fig. 4a; Table 1) which is similar to the Cretaceous field

379   direction. High-temperature components from the same clasts are scattered (Fig. 4b)

380   indicating these are the original magnetizations of the samples. These samples were used

381   to determine emplacement temperatures. Two samples from Site 4 displayed a two-

382   component magnetization where the low-temperature components are different to the

383   Cretaceous field direction. These are considered clasts which have either been moved

384   within the deposit or have been emplaced at ambient temperatures, and the two-component

385   magnetizations predate the emplacement. Due to this ambiguity, they have not been used

386   to provide emplacement temperature estimates. Sixty-seven samples display a single-

387   component (type-2) magnetization. All samples from NPK (n = 55; Sites 1 and 2) display

388   single-component magnetizations that are significantly grouped and have a mean direction

389   (D = 22.1°, I = -64.5°, α95 = 4.2°; Fig. 4c; Table 1) sub-parallel to the Cretaceous field

390   direction. These are interpreted to have been emplaced at temperatures greater than the

17

391   Curie temperature of the minerals present. The remaining type-2 behaviour clasts (n = 12)

392   exhibit single-component magnetizations that have random directions. These samples

393   should acquire a pTRM component parallel to the Cretaceous field direction because of the

394   well-distributed range of blocking temperatures. These are clasts interpreted to have been

395   emplaced at ambient temperatures (i.e. the single-component is the original magnetization

396   of the clasts which predates the eruption of the pipe). No groupings of single-component

397   and two-component magnetizations are observed at Site 3 (talus breccias; Fig. 4d) and Site

398   4 (SVK; Fig. 4e) and these deposits are interpreted to have been emplaced at ambient

399   temperatures. Eighteen samples display type-3 behaviour single-component

400   magnetizations with restricted blocking temperature spectra where no low-T_{ub} grains are

401   present. A thermal overprint would not be recorded in these clasts if they were emplaced at

402   temperatures less than the minimum $T_{ub.}$ Therefore, where the overprint in these clasts does

403   not parallel the Cretaceous field direction, the clasts provide minimum T_e estimates.

404

405   K2 and K1 pipes, Venetia Mine, South Africa

406

407   The thirty-five collected samples displayed weak remanent magnetizations with NRM

408   intensities ranging from 0.043 to 85 mA/m. The majority exhibited intensities of < 1

409   mA/m. A well-distributed range of NRM intensities is displayed by amphibolite, biotite

410   gneiss, argillite, and basalt clasts, with amphibolite samples showing both the lowest (0.043

411   mA/m) and highest (85 mA/m) measured NRM. All five garnetiferous biotite schist (GBS)

412   samples displayed NRM intensities < 0.5 mA/m. Dolerite clasts displayed stronger

413   intensities up to 82 mA/m, with five of the seven dolerite clasts displaying intensities > 10

18

414   mA/m. Twenty-four samples displayed stable magnetic behaviour in which a single or

415   two-component magnetization could be identified over a range of heating steps.

416   Homogeneous thermal demagnetization behaviour is displayed between all cores taken

417   from the same clast, except for biotite gneiss sample V53 from Site 4 (mVKBr) which gave

418   conflicting T_e estimates. The remaining eleven samples displayed erratic magnetizations,

419   with strongly fluctuating intensities, in which no stable magnetization components could be

420   identified. This behaviour is observed in all clast lithologies but restricted to the most

421   weakly magnetized samples (intensities < 0.5 mA/m), and probably results from low

422   signal-to-noise ratios within the samples. Garnetiferous biotite schist (GBS) samples

423   displayed the most erratic behaviour, exhibiting massive intensity spikes (increases) that

424   occur throughout the demagnetization process. Considerable mineralogical alteration

425   occurred in GBS clasts during the heating process and no samples from Site 10 were

426   including in any emplacement temperature determinations.

427

428   Of the twenty four samples that provided acceptable demagnetization results sixteen

429   samples were fully demagnetized to <5% of the original NRM intensity at a peak

430   temperature of 590°C. The remaining eight samples experienced unstable behaviour during

431   the heating process above ~400°C, most likely a result of mineralogical alteration. Low

432   temperature components could be identified and fitted in these samples.

433

434   Thermal demagnetization behaviour

435

436   Representative thermal demagnetization data for samples displaying stable single or two-

437   component magnetizations are shown in Fig. 5. Grouping of magnetization directions on

438   equal-area stereonets is shown in Fig. 6; statistical parameters are detailed in Table 1. Nine

439   samples display a well-defined two-component (type-1) magnetization. An example is

440   depicted in Fig. 5a for sample V2a (amphibolite; Site 8). In this example all points between

441   room temperature and 260°C can be fitted by a well-defined line (MAD = 8.1°) with a

442   direction (D = 322.7°, I = 31.7°), which is similar to a Cambrian reference palaeomagnetic

443   direction (D = 317.1°, I = 42.5°) for the Venetia area (Meert, 2003). The points from

444   300°C to the origin lie on a high-temperature line (MAD = 7.2°) with a direction (D =

445   68.3°, I = -11.4°), different from the low-temperature component. The emplacement

446   temperature (T_e) estimate uses the temperature range between the last point on the low-

447   temperature line and the second point on the high-temperature line, in this case T_e = 260–

448   300°C. The remaining eight type-1 samples display a well-defined two-component

449   magnetization but where the low-temperature component does not parallel the Cambrian

450   field direction. An example is shown for Fig 5b for sample V34b (biotite gneiss; Site 8). In

451   this case all points between room temperature and 420°C can be fitted by a well-defined

452   line (MAD = 8.3°) with a direction (D = 358.3°, I = -63.1°) that does not parallel the

453   Cambrian field direction, but, is parallel to the Mesozoic field direction for the region. All

454   points between 460°C and the origin can be fitted by a high-temperature line (MAD = 5.0°)

455   with a direction (D = 277.5°, I = -34.7°) that is different from both the low-temperature line

456   and the Cambrian field direction. Hence three interpretations are possible: a) the clast may

457   have been emplaced at elevated temperatures (420−460°C) within the deposit, with a

458   Cambrian overprint direction, but then moved within the deposit after it had cooled, with

20

459   the overprint direction fortuitously rotating to a Mesozoic field direction; b) the two-

460   component magnetization may have pre-existed in the clast, and it was emplaced at ambient

461   temperature; or c) the clast was emplaced at elevated temperature, but the Cambrian

462   overprint has itself later been overprinted by a Mesozoic field direction. Such a Mesozoic

463   overprint would likely be of chemical origin, and hence the sample cannot be used to

464   estimate a Cambrian emplacement temperature. Given that eight of the nine samples with a

465   stable two-component magnetizations yield low-temperature components that parallel the

466   Mesozoic field direction this is our preferred interpretation.

467

468   Two samples displayed stable single-component (type-2) magnetizations. An example is

469   depicted in Fig. 5c for sample V60a (amphibolite; Site 5). In this example a single

470   magnetization vector is defined by a well-fitted line (MAD = 6.1°) through all data points

471   from room temperature to the origin. The direction of the line (D = 308.4°, I = 22.3°) is

472   similar to the Meert (2003) Cambrian reference palaeomagnetic direction, implying the

473   clast was emplaced at temperatures greater than the maximum Curie temperatures of the

474   minerals it contains (in this case T_e >560°C). In three samples the natural magnetic grain

475   size distribution is extremely restricted and no grains with low unblocking temperatures

476   (T_{ub}) are present (type-3 behaviour). This is illustrated in Figs. 5d, e for Site 1dolerite

477   samples V18b and V19a respectively. In these samples little or no demagnetization occurs

478   in heating steps below 460°C, after which 90 % of the magnetization is removed. In

479   sample V18b (Fig. 5d) over 90% of the remanent magnetization is lost in heating between

480   500 and 590°C. As a TRM can only be recorded by high-T_{ub} grains in these samples, no

481   thermal overprint would be recorded in these clasts if heated to temperatures less than the

21

482   minimum T_{ub}. In sample V19a (Fig. 4e) all points between 460°C and the origin lie on a

483   well-fitted line (MAD = 5.0°) with a direction (D = 253.0°, I = 25.5°) which is sub-parallel

484   to the Cambrian field direction. This implies the clast was emplaced at a temperature

485   greater than the maximum Curie temperatures of the minerals it contained (T_e > 560°C).

486   However, in sample V18b (Fig. 5d) the direction of the magnetization (D = 274.1°, I = -

487   69.9°) is different to the Cambrian field direction, and, instead parallels the Mesozoic field

488   direction. This may suggest that this clast has been completely overprinted with a

489   Mesozoic direction. The remaining ten samples ("type-4" behaviour) display a restricted

490   range of blocking temperatures where no high-T_{ub} grains are present. This behaviour is

491   independent of clast type. Representative samples displaying this behaviour are shown in

492   Figs. 5f, g for samples V10a (argillite; Site 1) and V30a (biotite gneiss; Site 3) respectively.

493   In these samples 80% of the remanent magnetization is removed by heating to 220–340°C.

494   Well-defined lines can be fitted to a low-T_{ub} component, but no high-T_{ub} components can

495   be defined after 80% of the remanence is removed because the signal-to-noise ratio

496   becomes too low. Some samples are completely demagnetized at temperatures as low as

497   300°C (e.g. V10a; Fig. 5f) which indicates no ferromagnetic grains with T_{ub} >300°C are

498   present. However, only one of these samples yields an over print direction that is not

499   parallel to the Mesozoic field. In Site 1 amphibolite sample V23a (Fig 5h) a well-defined

500   (MAD = 9.6°) component with a direction D = 47.6°, I = 61.4° can be fitted to all points

501   from room temperature to 340°C, after which the magnetization of the sample becomes

502   erratic.

503

504   For the Venetia samples the emplacement temperature estimations are complicated by the

505   lack of samples displaying stable magnetic behaviour, preventing unbiased statistical

506   analysis of the magnetization components. As noted above there is a prevalence of low-

507   temperature components that parallel the Mesozoic field direction (Fig. 6a; Table 1). They

508   are likely of chemical origin and these samples cannot be used for emplacement

509   temperature determinations. This leaves us with only 4 samples, which have overprint

510   directions that might be Cambrian in age: one type-1 (V2a); one type-2 (V60a); one type-3

511   (V19a); and one type-4 (V23a). When these are combined they yield a mean-direction

512   declination of 308° and a mean inclination of 46° (Fig. 6b; Table 1), but the statistical

513   parameters are very poor, only just passing the Watson (1956) test for non-randomness

514   (Table 1). Nevertheless these four samples indicate emplacement temperatures of 260°C to

515   >560°C. The values are similar to that obtained at Orapa, and are taken to be supportive of

516   a range of emplacement temperatures of the kimberlite lithofacies, rather than being

517   diagnostic in their own right.

518

519   **Rock magnetism results**

520

521   Spurious emplacement temperature estimates may result from lithic clasts where the

522   magnetic mineralogy has been altered during or after emplacement. Newly formed or

523   chemically altered grains will acquire a chemical remanent magnetization (CRM) parallel

524   to Earth's magnetic field which may partly or completely overprint the existing

525   magnetization. The unblocking temperatures of these components may not coincide with

526   T_e but instead record the Curie temperatures (T_c) of new grains formed in a later (possibly

23

527 low-temperature) alteration event. To test the reliability of the emplacement temperature

528 results we determined the range of T_c values by measuring the variation in magnetic

529 susceptibility with temperature in 32 powdered samples from lithic clasts which provided

530 T_e estimates from the thermal demagnetization study. The Curie temperatures were

531 determined using the inverse-susceptibility method of Petrovský and Kapička (2006).

532

533 Representative magnetic susceptibility-temperature curves for 9 basalt lithic clasts sampled

534 from Orapa A/K1 and 2 amphibolite samples from Venetia K2 are shown in Fig. 7;

535 Demagnetization vector plots are also shown for three samples with T_e estimates ranging

536 from 240–280°C to 360–400°C. We find most basalt samples (n = 26) are dominated by

537 magnetite or Ti-poor titanomagnetites ($x_{Ti} \leq 0.1$) with T_c values of 559-595°C (e.g., Fig. 7a,

538 b, and f, h). Little or no alteration has occurred during heating or cooling of the samples,

539 although 11 samples show a higher susceptibility (but no change in T_c) after the experiment

540 (e.g., Fig. 7j, l). This is interpreted to result from the annealing of defects within the crystal

541 lattice of ferromagnetic minerals during heating (Bardot, 1997). The remaining basalt

542 samples (n= 4) with T_c values of 595-613°C could result from the oxidation of magnetite to

543 maghemite (or titanomagnetite to titanomaghemite) during the laboratory heating. The

544 main ferromagnetic minerals within amphibolite samples (n = 2) is titanomagnetite ($x_{Ti} \sim$

545 0.2) with T_c values of ~500°C (Fig. 6l, m). No spurious T_c values are observed to coincide

546 with the emplacement temperature estimates obtained during thermal demagnetization

547 which supports the validity of the emplacement temperature results.

548

549 **Petrography and textural relations**

24

550

551   The basalt lithic clasts contain ilmenite and titanomagnetite grains in roughly equal

552   proportions (total proportion 5–15%). Grain diameters vary from <1 μm to ~200 μm.

553   Ilmenite typically occurs as elongate grains (<100 μm length) and titanomagnetites as

554   subhedral to euhedral grains (10–200 μm diameter). Titanomagnetites invariably display

555   coarse or fine ilmenite lamellae along {111} crystallographic planes, and occasionally

556   contain inclusions of ilmenite with irregular or sharp boundaries parallel to the

557   crystallographic axes (Fig. 8a, b). The host titanomagnetite is enriched in Fe with

558   compositions approaching magnetite. These features are typical of deuteric oxidation of

559   host titanomagnetite grains (Ulvospinel-Magnetite solid solution) in igneous rocks

560   (Haggerty, 1991). The intergrowth textures dramatically reduce the effective grain size of

561   the host titanomagnetites (Fig. 8c, d) and it is likely a proportion of the thermal remnant

562   magnetization (TRM) is carried by these magnetite or Ti-poor titanomagnetite intergrowth

563   grains. These textures are mirrored in country rock samples (Fig. 8e, f), although finer

564   grained and skeletal titanomagnetites are observed in samples from basalt flow tops.

565   Collectively these observations indicate that there is no evidence of pervasive hydrothermal

566   alteration of primary igneous ferromagnetic grains or the growth of new ferromagnetic

567   species in the lithic clast samples. The oxides observed under the SEM, however, are larger

568   than those which typically carry stable magnetic remanence, which are normally in the sub-

569   μm size range and hence below the resolution of the SEM, but the fact that original igneous

570   textures are preserved gives us confidence that the primary magnetic mineralogy is likely

571   also preserved within the lithic clasts.

572

573   The amphibolite gneiss lithic clasts in Venetia K1 and K2 are upper amphibolite

574   metamorphic facies rocks of the Venetia Klippe unit (Barton et al., 2003). They show

575   compositional variability but typically display granoblastic textures containing hornblende

576   ± garnet + biotite ± feldspar ± quartz + ilmenite. Fe-Ti oxide proportions vary from <1% to

577   3%. Oxides occur as acicular grains in garnets and biotites (<100 μm length), or as larger

578   (≤300 μm) anhedral inclusions within hornblende grains (Figs. 8g, h). The grains are

579   typically host illmenite grains with bladed intergrowths of rutile and titanite, or fine grained

580   mottled intergrowths of Ti-poor titanomagnetite, rutile and illmenite. These textures and

581   assemblages are mirrored in samples of *in situ* amphibolite country rock. Therefore little

582   alteration of the metamorphic and ferromagnetic mineralogy of the lithic clasts is

583   considered to have occurred during their emplacement. The paucity of magnetite and

584   titanomagnetite in the samples accounts for weak magnetizations observed in the lithics.

585

586   **Emplacement temperatures and their interpretation**

587

588   Given the relative paucity of data from the Venetia pipes we focus on the results from the

589   Orapa A/K1 kimberlite pipe, Botswana. Palaeomagnetically determined T_e estimates

590   determined from individual lithic clasts are shown in Fig. 9. Single-component (type-2; n =

591   55) magnetizations in NPK basalt clasts provide minimum T_e estimates of >570°C to

592   >660°C for vent-filling pyroclastic breccias (Fig. 9a). Maximum T_e estimates of <180°C

593   (which is the lower limit of the palaeomagnetic method for these samples) are provided by

594   randomly orientated single-component and low-temperature component magnetizations (n

595   = 13) in SVK and talus breccia samples (Fig. 9b). These are interpreted to have been

26

596 emplaced at ambient temperatures. Well-defined two-component magnetizations (n = 23)

597 provide T_e estimates of 200–440° for lithic clasts within inner crater SVK deposits (Fig.

598 9b).

599

600 The results from NPK samples provide minimum deposit equilibrium temperatures (T_{dep}) of

601 >570°C which implies that the NPK is a primary pyroclastic deposit emplaced at

602 significantly elevated temperatures, as proposed by Field at al. (1997) based on field and

603 petrographic evidence. NPK rocks contain the typical metamorphic alteration assemblage

604 of serpentine and diopside which is constrained to be formed at temperatures <400°C

605 (Stripp et al., 2006). This lower estimate on the emplacement temperature of the deposits is

606 consistent with the deposits being emplaced at higher temperature (according to the TRM

607 results) with olivine, as the major component of the deposits, being stable. Later as the

608 deposits cooled down in a hydrothermal system olivine is replaced by serpentine to

609 generate the lower temperature assemblage. T_e estimates for SVK samples of <180°C in

610 talus breccias and <180°C to 200–440°C in volcaniclastic breccias implies that clasts were

611 emplaced in the south pipe at both ambient and elevated temperatures. This indicates both

612 epiclastic and pyroclastic depositional processes occurred in the south pipe. The result

613 from talus deposits is consistent with emplacement by epiclastic processes around the

614 margin of the pipe, as proposed by Field et al. (1997). Volcaniclastic breccias emplaced at

615 ambient temperatures within the inner crater are consistent with emplacement as rock-fall

616 and debris-flow deposits (Field et al., 1997; Gernon et al. 2009a). Clasts emplaced at

617 elevated temperatures (Site 5; Fig.1a and 2a) are located within a laterally extensive, 15–20

618 m thick kimberlite pyroclastic flow unit described by Gernon et al. (2009b). The unit lies

619   unconformably over crater-filling deposits, which postdate the eruption of the north pipe.

620   Gernon et al. (2009b) infer that the pyroclastic flow originated from a neighbouring

621   kimberlite pipe.

622

623   **Volcanological implications**

624

625   Results from Orapa A/K1 provide minimum T_{dep} values of >570°C for vent-filling

626   pyroclastic rocks. These samples were heated to temperatures greater than the Curie

627   temperatures of the minerals present and are observed to have reached thermal equilibrium

628   within the deposit. It is inferred that most, if not all, of the lithic clasts will have been

629   incorporated into the vent-filling pyroclastic deposits at ambient temperatures because the

630   conduit wall rock will have been cold prior to onset of volcanism. The mixing of cold lithic

631   clasts with erupting kimberlite magma will cool the erupting pyroclastic mixture (Marti et

632   al., 1991) as heat is shared out between the juvenile kimberlite pyroclasts and lithic clasts.

633   An idealised equilibrium temperature of the erupting mixture of pyroclastic and lithic

634   components, T_M, can be calculated from the heat conservation equation:

635

636    $$T_M = \frac{C_K\, T_K\, (1-x) - x C_L T_L}{C_L x + C_K (1-x)},$$

637

638   where T_K is the temperature of the kimberlite pyroclasts (assumed to be similar to

639   kimberlite magmatic temperatures of 1273-1473 K (Ferdochouk and Canil, 2004; Mitchell,

640   2008; Sparks et al., 2009), T_L is the initial temperature of the lithic clasts (293 K), x is the

641   mass fraction of lithic clasts entrained in the mixture, C_K is the specific heat capacity of

28

642 kimberlite pyroclastics ($C_{olivine}$ at 1000 K = 1150 J kg^{-1} K^{-1}; Gillet et al., 1991), and C_L is the

643 specific heat capacity of lithic clasts (C_{basalt} at 800 K = 1100 J kg^{-1} K^{-1}; Bouhifd et al.,

644 2007). The conversion of lithic clast volume to weight % was made using standard

645 densities for lithic clasts (ρ_{basalt} = 2900 kg m^{-3}), and kimberlite pyroclasts ($\rho_{olivine}$ = 3270 kg

646 m^{-3}). The average proportion of lithic clasts within vent-filling pyroclastic breccias is ~10–

647 20% (Walters et al., 2006; Brown et al., 2009). The bulk mixing of a juvenile magmatic

648 component with 10–20 % cold lithic clasts (x = 0.08–0.16) would reduce the temperature of

649 the mixture from magmatic temperatures of 1000°C to ~920-850°C. These values can be

650 considered maximum estimates of the T_{dep} of vent-filling deposits and therefore the vent-

651 filling deposits in A/K1 could have been 200–300°C hotter than the TRM estimates

652 (>570°C). T_e estimates for individual lithic clasts within the pyroclastic flow deposit in the

653 Orapa south pipe crater range from 200–440°C. The average lithic content of the

654 pyroclastic flow deposit is ~30% (Gernon et al., 2009b) and the ideal equilibrium

655 temperature for a mixture of juvenile magma at 1000°C and 30 vol.% (x = 0.25) cold lithic

656 clasts is ~760°C. The deposit is interpreted as a lithic breccia deposited rapidly upon

657 deceleration of a pyroclastic flow (Gernon et al., 2009b). The scatter in the observed T_e

658 estimates can be explained if some of the lithic clasts do not equilibrate with the flow

659 temperature during rapid transportation. Since the clasts were originally cold and were

660 heated up in the deposit, the upper T_e estimates of 400–440°C most closely represent the

661 equilibrium temperature of the deposit. Further cooling of the pyroclastic flow from source

662 temperatures of ~760°C to deposit equilibrium temperatures of 400–440°C can be

663 explained by air entrainment during transport, and does not necessitate the input of water

664 (Sparks et al., 1978).

665

666   The amount of cooling due to the incorporation and vapourisation of water into the

667   pyroclastic flow can be determined using the heat balance equation:

668

669
$$T_{dep} = T_M - \left[\frac{yC_{LW}(T_{100}-T_W)+yL_W+yC_{VW}(T_K-T_{100})}{C_M(1-y)}\right],$$

670

671

672   where T_M is the initial temperature of the pyroclastic mixture, T_W is the initial water

673   temperature (293 K) which will be heated to boiling point T_{100} (373K), y is the mass

674   fraction of water, L_W is the latent heat of vaporization of water (2.3×10^6 J kg^{-1}), C_{LW} is the

675   specific heat capacity of liquid water (4228 J kg^{-1} K^{-1}), C_M is the heat capacity of the

676   pyroclastic flow (assumed to be similar to kimberlite pyroclasts; $C_{olivine}$ at 1000 K = 1150 J

677   kg^{-1} K^{-1}), C_{VM} is the specific heat capacity of steam (2040 J kg^{-1} K^{-1}). Cooling of

678   approximately ~300°C from eruption to deposit equilibrium temperatures would require 10

679   wt. % liquid water.

680

681   **Conclusions**

682

683   Thermoremanent magnetism studies of lithic inclusions have successfully differentiated the

684   emplacement temperatures of a variety of volcaniclastic lithofacies preserved within the

685   Cretaceous Orapa kimberlite pipes (Fig. 10). Data from the Cambrian-aged Venetia pipe

686   are of a much lower quality, but they do not contradict the results from Orapa. Obtained

687   T_{dep} values are consistent with the field evidence of the various deposits (Field et al., 1997;

688   Brown et al., 2009; Gernon et al., 2009a). T_{dep} estimates for pyroclastic deposits are

689   consistent with previous estimates of kimberlite emplacement temperatures (≤340°C;

690   Sosman 1938; Watson 1967; McFadden, 1977; Stasiuk et al., 1999). The T_{dep} values

691   obtained for pipe-filling pyroclastic deposits (260–300°C to >570°C) are similar to the

692   emplacement temperatures of extrusive pyroclastic rocks erupted from more silicic volcanic

693   systems (Hoblitt and Kellogg, 1979; Banks and Hoblitt, 1981; Kent et al., 1981; Cioni et

694   al., 2004; McClelland et al., 2004; Scott and Glasspool, 2005). Pyroclastic deposits

695   become welded at high temperatures and this is particularly common in pyroclastic deposits

696   of low-viscosity magmas (Sumner 1998). Welding textures have recently been recognised

697   in some rocks in Venetia K2 pipe (Brown et al., 2008), providing further evidence of high

698   emplacement temperatures for some kimberlite pyroclastic deposits. Low T_{dep} estimates for

699   clasts in the SVK and talus breccias (<180°C), which show a single-component

700   magnetization, are consistent with emplacement at ambient temperatures by epiclastic

701   processes (rock fall and debris flow; Fig. 10; see Field et al., 1997; Gernon et al., 2009a).

702

703   Many kimberlite pipes exhibit evidence for multiple phases of eruptive activity (e.g., nested

704   and cross-cutting pyroclastic and breccia units (Venetia K2 and K1; Kurszlaukis and

705   Barnett, 2003; Brown et al., 2009; Koffiefontein, South Africa, Naidoo et al., 2004). The

706   periods between these phases of activity are unknown, but the presence of clasts with two-

707   component magnetizations may indicate that individual kimberlite pipes are active over

708   limited periods. The well-defined, two-component magnetizations could only have been

709   acquired if they had cooled in a stationary position, after the deposits had completely

710   stabilised and were not subsequently rotated or moved. Cooling times by conduction for

711   kimberlite pipe fills are estimated at decades to centuries (Sparks et al., 2006), thus, late-

712   stage disruptive volcanic activity must have taken place while the deposits were still hot or

713   after the deposits had cooled and lithified (by diagenesis and serpentinisation). The results

714   from are consistent with high temperature mineral assemblages of serpentine-diopside-

715   calcite-chlorite observed in these deposits, which indicate temperatures of 300-340°C

716   (Stripp et al., 2006).

717

718   The T_{dep} estimates for the pyroclastic deposits allow some constraints to be placed on the

719   eruption dynamics of studied kimberlite pipes. Minimum T_{dep} values of 260–300°C to

720   >570°C in the Venetia and Orapa pipes are consistent with volatile-driven explosive

721   eruptions. The temperatures of kimberlite magmas is now thought to be in the range of

722   1200-1000°C (Ferdochouk and Canil, 2006; Mitchell, 2008; Sparks et al., 2009). The

723   incorporation of 10–20% cold lithic clasts would cool the source pyroclastic mixture from

724   magmatic temperatures to 920–850°C. Therefore the actual temperatures of the primary

725   components of the vent-filling deposits may have been 200–300°C higher than the TRM

726   estimates. Similarly the Orapa south pipe contains a pyroclastic flow deposit with, on

727   average, 30 % lithic clasts (Gernon et al., 2009b) and so the original pyroclastic component

728   may have hotter by up to 300°C than the TRM estimates. The amount of cooling from

729   magmatic temperatures to the estimated deposit temperatures is typical of many other

730   pyroclastic deposits worldwide, and can be explained by the entrainment and heating of air

731   and cold lithic material. It is difficult to reconcile these elevated emplacement temperatures

732   with phreatomagmatic explosivity. Explosive interaction of ground or surface water with

733   rising magmas commonly cools erupting flows close to ambient (Thomas, 1993; Bardot et

734 al., 1996). Quantitative measurements of the emplacement temperatures of

735 phreatomagmatic deposits indicate values of <140°C (Thomas, 1993; Bardot et al., 1996;

736 Porreca et al., 2008) to as much as 275°C (De'Gennaro et al., 1996). Low temperatures in

737 phreatomagmatic deposits are also suggested by many features such as the inclusion of

738 uncharred wood in phreatomagmatic deposits (e.g., Giordano et al., 2002) and by the

739 plastering of wet ash onto obstacles (e.g., Cole et al., 2001). However, we stress that our

740 findings do not rule out phreatomagmatic explosivity during kimberlite eruptions.

741

742 This research demonstrates that thermoremanent studies of lithic inclusions can

743 successfully differentiate between epiclastic and pyroclastic deposits within ancient

744 kimberlite crater-fill successions. This may have important economic implications for the

745 mining and exploration of kimberlite bodies - not all deposits preserved within a volcanic

746 crater above a kimberlite pipe may be sourced directly from that pipe.

931   Orapa A/K1 kimberlite body (modified from Field et al., 1997 and Gernon et al., 2009a).

932   The body comprises two steep-sided pipes (north and south). **b** Simplified geological map

933   of the K2 kimberlite pipe, Venetia Mine, South Africa (from Brown et al., 2008). **c**

934   Geological map of K1 kimberlite pipe, Venetia Mine, South Africa. **Inset**: map of southern

935   Africa and locations of mines.

936

937   Figure 2. **a** Photograph of the Orapa A/K1 mine (looking south), showing the localities and

938   stratigraphic context of the sampled deposits (sampling sites are numbered). The wall rock

939   comprises Stormberg Formation basalts and Ntane Formation sandstones, the latter of

940   which crop out as a septum between the north and south pipes. **b** Photograph of the Venetia

941   K2 mine (looking northwest) showing the westward dipping shear surface which separates

942   the two halves of the pipe (K2 east and K2 west). Marked lithological contrasts occur

943   across the shear zone with massive volcaniclastic kimberlite (MVK) in contact with matrix-

944   supported volcaniclastic kimberlite breccias (mVKBr) on the lower bench, and with clast-

945   supported volcaniclastic kimberlite breccias (cVKBr) on upper bench. The sampling sites

946   which are within the field of view are numbered. **c** Photograph of the Venetia K1 mine

947   (looking northwest). K1 is predominately filled with MVK and the wall rock comprises

948   Proterozoic basement gneisses

949

950   Figure 3. Representative thermal demagnetization vector plots for basalt clasts from Orapa

951   A/K1. Solid squares represent the magnetization vector for each sample (projected on to the

952   horizontal plane) at different laboratory temperatures (in °C); open circles represent the

953   vector projected onto a vertical plane at the same laboratory temperature. **a, b** Type-1 two-

954   component magnetizations. **c, d** Two-component and single-component magnetization

955   obtained from exterior and interior of the same lithic clast. **e, f** Type-2 single component

956   magnetizations. **g, h** Type-3 (restricted T_{ub} spectra) single component magnetizations.

957

958   Figure 4. Equal area stereographic projections of palaeomagnetic directions recorded at

959   each sampling site at Orapa A/K1. Open symbols denote upper hemisphere projections;

960   solid symbols denote lower hemisphere projections. Small circle is the mean direction of

961   the data and the larger circle around the mean shows the 95% confidence limit of the mean

962   (expressed as an angular radius). Open star is the Cretaceous reference palaeomagnetic

963   direction (D = 350°, I = -69). **a** Low-temperature components in type-1 clasts from Site 5

964   (pyroclastic flow deposit). **b** High-temperature components in type-1 clasts from Site 5. **c**

965   Type-2 single component magnetizations from NPK clasts (Sites 1 and 2). **d** Single-

966   component magnetizations from Site 3 (Talus deposit). **e** Low-temperature and single

967   components from Site 4 (Debris flow deposit).

968

969   Figure 5. Representative thermal demagnetization vector plots for lithic clasts from Venetia

970   K1 and K2 pipes. Solid squares represent the magnetization vector for each sample

971   (projected on to the horizontal plane) at different laboratory temperatures (in °C); open

972   circles represent the vector projected onto a vertical plane at the same laboratory

973   temperature. **a,b** Type-1 two-component magnetization. **c** Type-2 single component

974   magnetization. **d, e** Type-3 (restricted T_{ub} spectra) single component magnetizations. **f, g, h**

975   Type-4 (restricted T_{ub} spectra) single component magnetizations.

976

977   Figure 6. Equal area stereographic projections of palaeomagnetic directions recorded at

978   each sampling site at Venetia K1 and K2. Open symbols denote upper hemisphere

979   projections; solid symbols denote lower hemisphere projections. Small circle is the mean

980   direction of data and the large circle around the mean shows the 95% confidence limit of

981   the mean (expressed as an angular radius). Solid star is the Cambrian reference

982   palaeomagnetic direction (D = 317.1°, I = 42.5°). Open star is the Cretaceous reference

983   palaeomagnetic reference direction (D = 350°, I = - 69°). **a** Mesozoic overprint directions in

984   Venetia K1 and K2 samples. **b** Cambrian overprint directions observed in 4 samples from

985   Venetia K1 and K2.

986

987 Figure 7. Typical magnetic susceptibility-temperature curves for samples from **a, b** Orapa

988 A/K1 SVK (Site 4), **c, d, f** Orapa A/K1 SVK (Site 5), **h, i** Orapa A/K1 NPK (Site 2), **j, k**

989 Orapa A/K1 SVK (Site 3), **l, m** Venetia K2. **e, g, n** Representative thermal demagnetization

990 plots for samples providing T_e estimates. The Curie temperatures (T_c) were determined

991 using the inverse-susceptibility method of Petrovský and Kapička (2006).

992

993 Figure 8. SEM micrographs of Fe-Ti oxides within basalt and amphibolite samples. **a** Host

994 titanomagnetite grain in basalt sample AK1-51a (T_e = 360-400°C); Ilmenite lamellae (dark

995 grey) are observed along {111} cystallographic axes of the host titanomagnetite (light

996 grey). **b** Host titanomagnetite grain in basalt sample AK1-76b2 (T_e ≥660°C). **c, d** Higher

997 magnification view of Ti-poor titanomagnetite intergrowths in AK1-51a and AK-76b2

998 respectively. **e, f** Country rock basalt samples. **g** Ilmenite grain in amphibolite gneiss

999 sample V60a (T_e ≥590°C) showing ilmenite, rutile and titanite intergrowths. The mottled

1000 regions are fine-grained intergrowths of Ti-poor titanomagnetite, rutile and illmenite. **h**

1001 Ilmenite grain in country rock amphibolites sample. *ilm* ilmenite, *rut* rutile, *ti* titanite, *tm*

1002 titanomagnetite.

1003

1004 Figure 9. T_e estimates obtained from individual lithic clasts. **a** Minimum T_e estimates

1005 obtained from Orapa A/K1 NPK lithic clasts provided by the maximum T_c of the minerals

1006 in the samples. The range of maximum T_c values and the number of individual samples

1007 displaying these values are shown. **b** T_e for individual samples in Orapa south pipe

1008 deposits. Downward pointing arrows indicate the data point is a maximum T_e estimate.

1009   Upward pointing arrows indicate the data point is a minimum T_e estimate. Error bars

1010   indicate the upper and lower limits of each T_e estimate obtained from clasts displaying a

1011   two-component magnetization. Open symbols are used to indicate where different T_e

1012   estimates have been obtained from a single clast.

1013

1014   Figure 10. Schematic illustration of the different T_{dep} estimates for the various deposits in

1015   the Orapa and Venetia kimberlite pipes. Vent-filling pyroclastic breccias provide minimum

1016 T_{dep} values of >570°C. Deposits interpreted as ignimbrites have intermediate T_{dep} values

1017   and epiclastic deposits (debris flows and talus breccias) have been emplaced at ambient

1018   temperatures (<180°C). Estimates of the source temperature of the pyroclastic deposits are

1019   ~760–920°C.

1020

1021   Table 1: Statistics of magnetization components from lithic clasts from the Orapa A/K1and

1022   the Venetia K1 and K2 kimberlite pipes.

1023

1024   N, number of magnetization vectors; n, total number of samples studied; **N**/n is the number

1025   of stable magnetization vectors identified per number of studied samples; Dec., declination

1026   of the mean direction of magnetization of N vectors; Inc., inclination of the mean direction

1027   of magnetization of N vectors; R, vector resultant of N vectors; k best estimate of precision

1028   parameter; α_{95}, 95% confident limit; R_0 Watson's (1956) parameter; grouping is random for

1029   N vectors if $R<R_o$; asterisk*, too few data are available to calculate accurate statistical

1030   parameters (N<4)
