ABSTRACT
We measure the bulk flow of the local Universe using the 6dF Galaxy Survey peculiar velocity sample (6dFGSv), the largest and most homogeneous peculiar velocity sample to date. 6dFGSv is a Fundamental Plane sample of $\sim 10^4$ peculiar velocities covering the whole Southern hemisphere for galactic latitude $|b| > 10^\circ$, out to redshift $z = 0.0537$. We apply the ‘minimum variance’ bulk flow weighting method, which allows us to make a robust measurement of the bulk flow on scales of 50 and 70 $h^{-1}$ Mpc. We investigate and correct for potential bias due to the lognormal velocity uncertainties, and verify our method by constructing a cold dark matter ($\Lambda CDM$) 6dFGSv mock catalogues incorporating the survey selection function. For a hemisphere of radius 50 $h^{-1}$ Mpc we find a bulk flow amplitude of $U = 248 \pm 58$ km s$^{-1}$ in the direction $(l, b) = (318^\circ \pm 20^\circ, 40^\circ \pm 13^\circ)$, and for 70 $h^{-1}$ Mpc we find $U = 243 \pm 58$ km s$^{-1}$, in the same direction. Our measurement gives us a constraint on $\sigma_8$ of $1.01^{+1.07}_{-0.58}$. Our results are in agreement with other recent measurements of the direction of the bulk flow, and our measured amplitude is consistent with a $\Lambda CDM$ prediction.

Key words: surveys – galaxies: kinematics and dynamics – galaxies: statistics – cosmology: observations – large-scale structure of Universe.

1 INTRODUCTION
The standard model of cosmology, $\Lambda$ cold dark matter ($\Lambda CDM$) is now well supported by a wide variety of observational probes, yet questions still remain about the nature of dark matter, and whether the observed cosmic expansion is caused by a cosmological constant, $\Lambda$, or some other form of dark energy. Galaxy peculiar velocities are one of the only probes of large-scale structure in the nearby Universe, and are gaining interest as a promising cosmological probe that offers new information on these problems at low redshift. Peculiar velocities are the motions of galaxies caused by gravitational infall into local matter overdensities. They are usually measured statistically via redshift-space distortions (Kaiser 1987; Peacock et al. 2001; Tegmark et al. 2004; Guzzo et al. 2008) but can also be measured directly. The line-of-sight component of the
peculiar velocity \( \mathbf{v} \) of a galaxy at position \( r \) is given by
\[
\mathbf{v} \equiv \mathbf{v} \cdot \hat{r} = c \left( \frac{z_{\text{obs}} - z_r}{1 + z_r} \right),
\]
where \( c \) is the speed of light, \( z_{\text{obs}} \) is the observed redshift, measured spectroscopically and corrected to the cosmic microwave background (CMB) rest frame, and \( z_r \) is the redshift corresponding to the real-space comoving distance \( r \) of the galaxy.\(^1\) The hat on \( \hat{r} \) denotes the unit vector.

In the linear regime, the velocity field \( \mathbf{v}(r) \) is directly related to the density field \( \delta(r) \), via ( Peebles 1980)
\[
\mathbf{v}(r) = \frac{H_0 a f}{4\pi} \int d^3r \frac{\delta(r')(r' - r)}{|r' - r|^3},
\]
where \( f \equiv \frac{\text{d} \ln D}{\text{d} \ln a} \) is the present-day growth rate of cosmic structure (in terms of the linear growth factor \( D \) and cosmic scale factor \( a \)), and \( \delta(r) = \frac{\bar{\rho}(r) - \bar{\rho}}{\bar{\rho}} \) with \( \bar{\rho} \) the average density of the Universe. Peculiar velocity measurements therefore allow us to trace the total matter distribution, including dark matter, without the complication of galaxy bias, and over a large range of scales. They also probe the nature of gravity through the growth rate \( f \).

The dipole of the velocity field or ‘bulk flow’ is particularly interesting since it measures the large-scale streaming motion of matter in the local Universe, which is sensitive to the large-scale modes of the matter power spectrum, and the matter density. There has been a lot of interest in the bulk flow on scales of 50–100 h\(^{-1}\) Mpc, since some authors have suggested it is larger than expected in \( \Lambda \)CDM; however, there has been a history of conflicting results in the literature. Some early measurements gave indications of apparently large bulk flows (Rubin et al. 1976; Dressler et al. 1987a; Lynden-Bell et al. 1988), while others found values consistent with predictions (Hart & Davies 1982; da Vauoulcours & Peters 1984; Aaronson et al. 1986) – see Kaiser (1988) and Strauss & Willick (1995) for a review of early measurements. More recently, an increase in the amount and quality of peculiar velocity data has led to a surge of new measurements. Again, some of these claimed to find evidence of an unusually large bulk flow (Kashlinsky et al. 2008; Watkins, Feldman & Hudson 2009; Feldman, Watkins & Hudson 2010; Abate & Feldman 2012), while most find results consistent with \( \Lambda \)CDM (Colin et al. 2011; Dai, Kinney & Stojkovic 2011; Nusser & Davis 2011; Osborne et al. 2011; Turnbull et al. 2012; Lavaux, Afshordi & Hudson 2013; Ma & Scott 2013; Carrick et al. 2015; Feix, Nusser & Branchini 2014; Hong et al. 2014; Ma & Pan 2014; Planck Collaboration XIII 2014).

Some reported detections of unusually large bulk flows have been directly challenged. Kashlinsky et al. (2008) claimed to find a large dipole in the Wilkinson Microwave Anisotropy Probe (WMAP) kinetic Sunyaev–Zel’dovich (kSZ) effect, indicating a bulk flow of 600–1000 km s\(^{-1}\) out to \( z \sim 0.1 \), while Keisler (2009) showed their uncertainties were underestimated, reducing the significance of their result. Watkins et al. (2009) combined several different peculiar velocity catalogues, and used a ‘minimum variance’ (MV) bulk flow estimator to find a bulk flow of 407 km s\(^{-1}\) on a scale of 50 h\(^{-1}\) Mpc, while Ma & Scott (2013) repeated their analysis using a hyperparameter method to combine the surveys, along with a different choice of velocity dispersion parameter, and found a smaller bulk flow consistent with \( \Lambda \)CDM. Large-scale bulk flows also appear to contradict measurements of large-scale homogeneity in the galaxy distribution by Hogg et al. (2005) and Scrimgeour et al. (2012). Hence, although a large bulk flow remains an intriguing possibility, it could be attributed to unaccounted for systematic or statistical errors in existing measurements.

Another aim of measuring the large-scale bulk flow is to put in context the motion of the Local Group (LG) with respect to the CMB, i.e. the bulk flow on the scale of a few Mpc. The LG motion is \( 627 \pm 22 \) km s\(^{-1}\) towards \( l = 276^\circ \pm 3^\circ \), \( b = 30^\circ \pm 2^\circ \) (Kogut et al. 1993). In the gravitational instability model of linear theory, this is expected to be influenced by both nearby and large-scale structures, and would converge to the CMB dipole when averaging over a region of sufficiently large radius. However, attempts to reconstruct the CMB dipole using the density field have been inconsistent. Studies have suggested that it is necessary to go to scales of at least that of the Shapley Supercluster at 150 h\(^{-1}\) Mpc to recover the dipole motion (Kocevski & Ebeling 2006; Muñoz & Loeb 2008; Lavaux et al. 2010) while Erdogdu et al. (2006a,b) suggest only \( \sim 30 \) per cent of the motion is due to structures beyond 50 h\(^{-1}\) Mpc. Other studies show no convergence up to 200–300 h\(^{-1}\) Mpc (Bilicki et al. 2011; Nusser, Davis & Branchini 2014).

In this work we aim to shine new light on the local bulk flow, using peculiar velocity data from the 6-degree Field Galaxy Survey (6dFGS; Jones et al. 2004; Magoulas et al. 2012). This data set is the largest, most homogeneously derived peculiar velocity sample to date, with 888 Fundamental Plane (FP) distances. We apply the optimal MV weighting method proposed by Watkins et al. (2009) and Feldman et al. (2010) to measure the bulk flow.

This paper is structured as follows. In Section 2 we describe the 6dFGS Galaxy Survey peculiar velocity sample (6dFGSv). In Section 3 we explain how we derive peculiar velocities from the logarithmic distances, and our method of defining the velocity uncertainty of each galaxy to avoid bias in the estimated bulk flow. In Section 4 we describe the maximum likelihood and MV methods that we use to estimate the bulk flow. In Section 5 we describe our \( \Lambda \)CDM-based 6dFGSv mock catalogues. We present and discuss our results in Section 6 and conclude in Section 7.

Throughout this work we assume a flat \( \Lambda \)CDM cosmology with parameters from the Planck 2013 data release of \( \Omega_m = 0.3175 \), \( \Omega_{\Lambda} = 0.6825 \), \( \sigma_8 = 0.8344 \), and \( H_0 = 100h \) km s\(^{-1}\) Mpc\(^{-1}\) with \( h = 0.67 \). We only use this cosmology when converting between distance and redshift, and for comparing our bulk flow results with the \( \Lambda \)CDM predicted velocity dispersion. Since 6dFGSv is at low redshift (\( z \leq 0.054 \)) the results are only weakly dependent on the values of the cosmological parameters we assume. The uncertainties on these parameters are also significantly smaller than the uncertainties on our measurement, assuming a \( \Lambda \)CDM model, and so we fix these parameters throughout this work, since varying them would have a negligible effect.

### 2 6dFGS PECULIAR VELOCITY SAMPLE

The 6dFGS is a combined redshift and peculiar velocity survey of almost the whole Southern hemisphere, performed using the Six-Degree Field (6dF) multiﬁbre spectrograph on the UK Schmidt Telescope from 2001 May to 2006 January (Jones et al. 2004, 2006, 2009). The survey covers galactic latitudes \( |b| > 10^\circ \) out to a redshift of \( z \sim 0.15 \). The redshift survey (6dFGS) contains 125 071 near-infrared (NIR) and optically selected spectroscopic galaxy redshifts, over 17 000 deg\(^2\) and with a median redshift of 0.053. Targets were selected in the \( JHK \) bands from the Two Micron All Sky Survey...
Extended Source Catalog (2MASS XSC; Jarrett et al. 2000), with secondary samples in the $b_i$ and $r_i$ bands.

The peculiar velocity sample, denoted 6dFGSv (Campbell 2009; Campbell et al. 2014), is a subset of 8885 bright, early-type galaxies for which distances were derived using the FP relation. This sample was drawn from $\sim$11000 galaxies in 6dFGSz with measured FP data, in the form of velocity dispersions and photometric scale lengths (Campbell et al. 2014). The sample was selected by requiring good redshift quality ($Q = 3$–5), J-band magnitude $J < 13.75$, redshifts less than $16500$ km s$^{-1}$ (or $z < 0.0537$), and velocity dispersions larger than $\sigma_0 \geq 112$ km s$^{-1}$, with signal-to-noise ratio $S/N > 5$ Å$^{-1}$.

The redshift distribution of 6dFGSz compared to that of the parent J-band 6dFGSz sample is shown in Fig. 1. The fitting of the FP and peculiar velocity samples are described in detail in Magoulas et al. (2012, hereafter M12). The derivation of the FP distances and peculiar velocities, and correction for Malmquist bias and other selection effects, is described in Springob et al. (2014, hereafter S14).

3 DERIVING PECULIAR VELOCITIES FOR 6dFGSv

The output of the FP peculiar velocity derivation for 6dFGSv (from S14) is a probability distribution for the ‘logarithmic distance ratio’

$$\eta \equiv \log_{10}(D_c/D_r),$$

where $D_c$ is the comoving distance in the fiducial $\Lambda$CDM cosmology corresponding to the observed redshift $z$, while $D_r$ is the comoving distance corresponding to the angular diameter distance inferred from the FP.

Instead of obtaining $\eta$ as a single value with an uncertainty, S14 derive the full posterior probability distributions $P(\eta)$, in order to retain all the available information resulting from the selection cuts on the FP. These probability distributions are close to Gaussian in log distance, with a small skew due to the different selection effects and bias corrections, as described in S14.

The optimal MV estimator we wish to use for the bulk flow measurement, described in the next section, takes as input peculiar velocities in km s$^{-1}$. To convert $\eta$ to peculiar velocity $v$, we use the fact that

$$(1 + z) = (1 + z_r)(1 + z_0),$$

where $z_r$ is the redshift corresponding to $D_r$ in the assumed cosmology, and $z_0$ is the ‘peculiar redshift’, $z_0 = v/c$, where $v$ is the line-of-sight component of the galaxy’s peculiar velocity. The relation between redshift and comoving distance is

$$D(z) = \frac{c}{H_0} \int_0^z \frac{dz'}{E(z')},$$

where

$$E(z) = \frac{H(z)}{H_0} = [\Omega_m(1 + z)^3 + \Omega_{\Lambda}]^{1/2}$$

for which we use the fiducial $\Lambda$CDM parameter values listed in Section 1.

The peculiar velocity $v$ corresponding to $\eta$ is then

$$v(\eta, z) = c \left( \frac{z - z_r(\eta, z)}{1 + z_r(\eta, z)} \right),$$

with $z_r$ obtained from $\eta$ and $z$ using equations (3) and (5). This relation for $v(\eta, z)$ is illustrated for the 6dFGSv sample in Fig. 2.

We see that $v(\eta, z)$ is non-linear at fixed redshift, which poses a problem for obtaining an unbiased estimate of $v$. The observable quantity $\eta$ has Gaussian uncertainty in log-space, which translates to lognormal uncertainty on $v$. This is a standard problem for peculiar velocity measurements.

We can see this by converting the $P(\eta)$ distributions to probability distributions of velocity, $P(v)$, using the relation

$$P(v) = P(\eta) \frac{d\eta}{dv} = P(\eta) \frac{1}{D_c \ln(10)} \frac{dD_c}{dz} \frac{(1 + z_r)^2}{c(1 + z)}.$$

where $\ln$ is the natural logarithm. A typical velocity probability distribution $P(v)$ is illustrated in Fig. 3, where we have set $\langle \eta \rangle = 0$. The distribution is close to lognormal.

We obtain the peculiar velocity for each galaxy by taking the mean value of the $P(\eta)$ distribution, $\langle \eta \rangle = \int_{-\infty}^{\infty} \eta P(\eta)d\eta$, and converting it to velocity using equation (7). This is equivalent to the median of the $P(v)$ distribution, as can be seen in Fig. 3. This is the least biased way to determine velocity, correctly giving zero $v$ for zero $\eta$, and it is also the standard method used in the literature.

Since the uncertainty on $\eta$ is Gaussian, the uncertainty on $v$ is lognormal, and is proportional to $D_r$. The uncertainty on $v$, as

Figure 1. Redshift distribution of the 6dFGS peculiar velocity sample (6dFGSv, solid red histogram) compared to the parent J-band spectroscopic sample (6dFGSz, black line histogram). The vertical dashed line shows the redshift cut imposed on the velocity sample.

Figure 2. Radial peculiar velocity $v$ from equation (7), as a function of the mean $\eta$ value of each galaxy, $\langle \eta \rangle$, for the 6dFGSv sample, colour coded by redshift distance $D_c$. The $v(\eta)$ relation is single valued and monotonic for a given $D_c$, and is increasingly non-linear for increasing $D_c$. 

MNRA 455, 386–401 (2016)
the weights assigned to each galaxy in the bulk flow estimation are derived depending on the galaxy’s velocity uncertainty. If the weights were correlated with the velocities themselves, this would produce a biased bulk flow measurement, made worse if the redshift distribution of galaxies is not evenly distributed over the sky, as in 6dFGS.

4 BULK FLOW ESTIMATORS

The bulk flow is the average peculiar velocity in a given volume of space, usually taken to be a spherical region centred on us, and defined by

\[ U(R) = \frac{3}{4\pi R^3} \int_{x=0}^{R} v(x) d^3x, \]

where \( R \) is the radius of the sphere in which the bulk flow is measured. In practice, however, we can never perfectly sample the velocity field. Peculiar velocity samples are typically sparse, with complicated geometries and large measurement uncertainties. Additionally, we only observe the line-of-sight component of the peculiar velocities.

Different bulk flow estimators have been suggested in the literature to account for this, including the maximum likelihood estimate (MLE; Dressler et al. 1987b; Kaiser 1988), comparison with the density field (Bertschinger et al. 1990; Willick & Strauss 1998; Dekel et al. 1999; Turnbull et al. 2012), reconstruction of the velocity field based on a velocity power spectrum (Nusser & Davis 2011), and the so-called MV weighting method (Watkins et al. 2009; Feldman et al. 2010).

In this paper we apply the MLE and the MV method to 6dFGSv. These both evaluate the bulk flow as a weighted sum of the peculiar velocities. Given a sample of objects with radial peculiar velocities \( v_n \), these methods assign a weight \( w_{i,n} \) corresponding to the \( i \)th direction for each galaxy. The bulk flow \( \mathbf{U} = (u_x, u_y, u_z) \) is then

\[ u_i = \sum_n w_{i,n} v_n. \]

In the following two subsections we give an overview of these two weighting methods.

A parallel analysis of the 6dFGSv bulk flow is currently being made by Magoulas et al. (in preparation), who apply a different bulk flow estimation method. They use forward modelling, performing a maximum likelihood fit to a bulk flow model transformed into the observational space of the FP parameters. This approach effectively fits the measured logarithmic distance ratios \( \eta = \log(D_x/D_z) \) without converting to linear velocities, and can fully account for the (Gaussian) error distribution in the observational space.

4.1 Maximum likelihood estimate

The MLE has traditionally been the most common technique used to measure the bulk flow. We consider here the MLE using inverse variance weighting from Kaiser (1988). Given a sample of \( N \) objects at positions \( r_{i,n} \), each having a measured line-of-sight velocity \( v_n \) with uncertainty \( \sigma_n \), the MLE weight for the \( n \)th galaxy is

\[ w_{i,n} = \sum_j A_{i,j}^{-1} \frac{r_{i,j}}{\sigma_n^2 + \sigma_{\epsilon}^2}, \]

where

\[ A_{i,j} = \sum_n \frac{r_{i,n} r_{i,j}}{\sigma_n^2 + \sigma_{\epsilon}^2}. \]
The parameter $\sigma_v$ is the 1D velocity dispersion, usually assumed to be $\sim 300$ km s$^{-1}$; we assume galaxies have random motions drawn from a Gaussian distribution with this dispersion, in addition to the bulk flow component. These random motions add to the noise for any given galaxy.

This solution makes a number of simplifying assumptions:

(i) the observational errors, $\sigma_n$, are Gaussian;
(ii) linear theory holds, so $v_n \ll H_0 r_n$;
(iii) we can neglect uncertainty in $r_i$;
(iv) $u_i$ is fairly insensitive to small-scale velocities, and that $\sigma_u$, which will be strongly influenced by non-linear flows, can be fixed at a given value.

In practice, nearly all of these assumptions will be violated to some extent. The observational errors on $v$ are not Gaussian, $v \sim 20$–30 per cent of $H_0 r$, and linear theory does not strictly apply, since $\sigma_v \sim 300$ km s$^{-1}$ is comparable to the expected bulk flow amplitude on the scales we measure. However, we do not expect these to have a significant impact on our measurement. Since our analysis is done in redshift space, the uncertainty on $r_i$ is the uncertainty on the redshift distance, which is indeed negligible. We find that our result is insensitive to the choice of $\sigma_u$, which we discuss further in Section 4.4. We leave further analysis of non-Gaussian uncertainties to future work.

4.2 Minimum variance method

Although the MLE is simple to perform, it has several disadvantages. It will have a complex window function dependent on the geometry and uncertainties of a particular survey, making it difficult to compare between surveys and with theory. It is also density-weighted rather than volume-weighted, as it tends to up-weight high-density regions where galaxies are more likely to be measured, and down-weight low-density regions. Finally, because it is fairly insensitive to small-scale velocities, and that $\sigma_u$, which will be strongly influenced by non-linear flows (Agarwal, Feldman & Watkins 2012).

The parameter $\sigma_v$ is the 1D velocity dispersion, usually assumed to be $\sim 300$ km s$^{-1}$; we assume galaxies have random motions drawn from a Gaussian distribution with this dispersion, in addition to the bulk flow component. These random motions add to the noise for any given galaxy.

The parameter $\sigma_v$ is the 1D velocity dispersion, usually assumed to be $\sim 300$ km s$^{-1}$; we assume galaxies have random motions drawn from a Gaussian distribution with this dispersion, in addition to the bulk flow component. These random motions add to the noise for any given galaxy.
the error on the bulk flow magnitude is $\sigma$ down-weighted by the ideal window function, the smallest velocity errors, but in the MV method where these are the weights of nearby galaxies most strongly, since they have the $\sigma$ et al. (2014) perform a fit to $\sigma$ 'add back in' this uncertainty in our bulk flow weights. Johnson the uncertainty in the fitting of the FP by M12 and S14, and is effectively subtracted from the uncertainty in the estimation $\sigma$ of the plane. A value of $\sigma$ for in the fitting of the FP, since the fitting is done assuming each $\sigma$ ∼ flow on the order of $\sigma$ per cent. We therefore fix $\sigma$ 250 km s$^{-1}$ for our analysis.

5 6dFGSv SELECTION FUNCTION AND ΛCDM MOCK CATALOGUES

In order to test possible systematics in our bulk flow measurement arising from the survey selection function, we apply our bulk flow analysis to ΛCDM mock catalogues of 6dFGSv, incorporating the survey selection function. To create ΛCDM peculiar velocity mocks, we need to make use of an $N$-body simulation which provides both the positions and velocities of galaxies. In this section we describe how we determine the selection function of 6dFGSv, and use this to generate mock catalogues using the GiggleZ $N$-body simulation. This selection function also allows for the creation of random catalogues for clustering analysis.

5.1 6dFGSv survey selection function

The selection function $W(x)$ is a function indicating the expected number density of 6dFGSv galaxies at a position $x$, due to the different selection criteria of the sample. These can be both angular and redshift dependent. To implement the selection function in our mocks, we reproduce the selection process described in M12 and S14 to obtain the 6dFGSv sample of 8885 galaxies from the full 6dFGS redshift sample of 125 000 galaxies. In summary, they first select galaxies suitable for fitting the FP, by choosing galaxies with reliable redshifts (with redshift quality $Q = 3–5$) and redshifts less than 16 500 km s$^{-1}$ (or $z < 0.0537$), above which a key spectral feature used to measure velocity dispersion is shifted out of the wavelength range. They then morphologically select early-type (E/S0) galaxies, by matching the observed spectra to template galaxy spectra. This produced a sample of ∼20 000 galaxies. These ∼20 000 galaxies then had their velocity dispersions measured using the Fourier cross-correlation technique (Campbell 2009). Of these, galaxies with a signal-to-noise ratio $S/N > 5$ Å$^{-1}$, and velocity dispersions larger than the instrumental resolution limit ($s \geq 2.05$, or $\sigma_s \geq 112$ km s$^{-1}$ were selected, to produce a ‘FP sample’ of 11 287 galaxies. This sample, with both spectroscopic measurements from 6dFGS and photometric measurements from 2MASS in the $J$, $H$, and $K$ bands, was used by M12 for the fitting of the FP parameters.

Finally, the peculiar velocity sample 6dFGSv was obtained from the FP sample after several further cuts. A stricter redshift limit of $cz < 16120$ (ζ < 0.0537) was imposed in the CMB frame, along with further magnitude cuts of $J \leq 13.65$, $H \leq 12.85$, and $K \leq 12.55$, to maintain high completeness over the sky. Further galaxies were removed after a visual inspection, and a velocity dispersion $\chi^c$ cut, to obtain the final peculiar velocity sample of 8885 galaxies.

5.2 Fundamental Plane fitting

Here we introduce the FP relation we will use in making the mocks – see M12 for further details. The FP relation can be written in logarithmic units as

$$r = as + bi + c,$$

where $r \equiv \log R_c$, $s \equiv \log \sigma_s$, and $i \equiv \log (L_s)$, where $R_c$ is the effective radius in units of $h^{-1}$ kpc, $\sigma_s$ is the central velocity dispersion in units of km s$^{-1}$, and $(L_s)$ is the mean surface brightness, in units of $L_\odot$ pc$^{-2}$. The coefficients $a$ and $b$ are the slopes of the plane and $c$ is the offset of the plane. M12 use logarithms of base 10.

M12 determine the FP parameters for 6dFGSv using a maximum likelihood fit to a 3D Gaussian model. The FP can be described either in terms of the observational parameters ($r, s, i$), or in terms of...
the three unit vectors corresponding to the axes of the 3D Gaussian describing the galaxy distribution. M12 refer to these as ‘FP-space’ and ‘u-space’, respectively. The model can then be described by eight parameters: \([a, b, c, \bar{r}, \bar{s}, \bar{t}, \sigma_1, \sigma_2, \sigma_3]\), where \((\bar{r}, \bar{s}, \bar{t})\) define the centre of the 3D Gaussian in FP-space and \((\sigma_1, \sigma_2, \sigma_3)\) are the dispersion of the Gaussian along each of the three axes in u-space. The offset of the FP can be calculated as \(c = \bar{r} - a \bar{s} - b \bar{t}\).

5.3 Mock sample algorithm

We create mock \(\Lambda\)CDM realizations of the 6dFGSv data set for the set of FP parameters \([a, b, c, \bar{r}, \bar{s}, \bar{t}, \sigma_1, \sigma_2, \sigma_3]\) derived by M12. We use the following steps to reproduce the 6dFGSv selection function and generate the mock catalogue.

(i) For a \(\Lambda\)CDM mock, start by drawing haloes from an N-body simulation in a mass range equivalent to the 6dFGS elliptical galaxies, i.e. pick haloes that match the bias of 6dFGS (this is effectively a cut in morphological type).

Angular and redshift cuts

(ii) Define the location of the observer, and calculate RA, Dec., true comoving distance \(D_c\), and radial peculiar velocity \(v\) for each galaxy. Also calculate the true and observed redshifts \(z_t\), \(z\), using equation (4).

(iii) Only include haloes within hard angular cuts Dec. < 0° and Galactic latitude \(|b| > 10°\).

(iv) Impose a redshift cut of \(cz < 16 \, 120 \, \text{km s}^{-1}\).

(v) Normalise by applying a random subsampling to obtain the number of galaxies in the 6dFGS parent redshift sample.

Magnitude and velocity dispersion cuts

(vi) For each galaxy, draw values for \(v_{1}, v_{2}\), and \(v_3\) from a 3D Gaussian with standard deviations \(\sigma_1, \sigma_2,\) and \(\sigma_3\) as listed in table 3 of M12. We use the \(J\)-band values as the \(J\) band has the smallest photometric errors.

(vii) Transform these values from the \(u\)-space (principal axes) coordinate system to the \([r, s, i]\)-space (observed parameters) coordinate system using the inverse of equation (6) in M12, with the specified FP slopes \((a, b)\) and FP mean values \((\bar{r}, \bar{s}, \bar{t})\). This gives the true FP parameters \((r_t, s_t, i_t)\) for the simulated galaxies.

(viii) Re-order each set of \((r_t, s_t, i_t)\) parameters in descending order of luminosity,

\[
\log L = 2\theta + i, 
\]

and assign them to the haloes in descending order of maximum circular velocity \(V_{\text{max,sub}}\).

(ix) Use the comoving distance \(D_c\) of each galaxy from the observer to determine the angular distance \(\theta\) from the physical radius \(r_t\), by calculating the angular diameter distance \(D_\Lambda\):

\[
D_\Lambda = \frac{r_t}{\theta} = \frac{D_c}{1 + \frac{z}{\Omega}}.
\]

(this relation is true for \(\Omega = 0\); see Hogg 1999). Then \(\theta\) is obtained from

\[
\log \theta = \log r_t - \log D_\Lambda.
\]

(x) Determine the true apparent magnitude \(m_t\) from the angular radius \(\theta\) and the degraded surface brightness \(i\) using

\[
m_t = \langle \mu_i \rangle - 2.5 \log [2\text{m}\theta^2].
\]

where \(\langle \mu_i \rangle = M - 2.5i + 21.57\), where \(M = 3.67\) for the \(J\) band. The surface brightness \(i\) is first degraded by ‘decorrecting’ for K-correction and surface brightness dimming.

Figure 6. The mean redshift distribution of our 20 GiggleZ mocks (black histogram), along with the standard deviation (blue dot–dashed histograms), compared to 6dFGSv (solid grey histogram).

(xii) Obtain the correlated measurement uncertainties in \(r, s,\) and \(i, (\epsilon_r, \epsilon_s, \epsilon_i)\), from the magnitude \(m_t\), using the matrix in equation (13) of M12.

(xiii) Only include galaxies with velocity dispersion \(s_v > \log (116 \, \text{km s}^{-1})\) (cut for instrumental resolution).

(xiv) Determine the observed magnitude \(m_o\) using the observed values \(r_o, s_o, i_o\).

(xv) Keep the galaxy if the observed magnitude \(m_o\) is brighter than the faint limit for the velocity sample \((J \leq 13.65)\).

(xvi) Use the selection function described in Jones et al. (2006) to determine the angular completeness of the 6dFGS spectroscopic follow-up, given the (RA, Dec., \(m_o\)) values for each galaxy. Sub-sample the galaxies with this probability.

(xvii) Apply a random subsampling to account for cuts in signal-to-noise ratio (S/N) and \(R\).

5.4 The mocks

In order to generate \(\Lambda\)CDM mocks, we apply our mock sample algorithm to the GiggleZ (Giga-parsec WiggleZ) simulation. GiggleZ (Poole et al. 2014) is a suite of dark matter N-body simulations run at Swinburne University of Technology. It has a WMAP-5 cosmology with \((\Omega_\Lambda, \Omega_m, \Omega_r, h, \sigma_8, n) = (0.727, 0.273, 0.0456, 0.705, 0.812, 0.960)\). We use the GiggleZ main simulation, which contains 2160 dark matter particles in a periodic box of side \(1 \, h^{-1}\) Gpc. The particle mass is \(7.5 \times 10^9 h^{-1} M_\odot\), which allows bound systems with masses \(\gtrsim 1.5 \times 10^{11} h^{-1} M_\odot\) to be resolved.

Halo finding for GiggleZ was performed using SUBFIND (Springel, Yoshida & White 2001), which utilises a friends-of-friends (FoF) algorithm to identify coherent overdensities of particles and a substructure analysis to determine bound overdensities within each FoF halo. We place a galaxy at the centre of each subhalo, and rank-order them by their maximum circular velocity \(V_{\text{max,sub}}\) to obtain the largest haloes, in order to reproduce the bias of the 6dFGSv sample.

We have generated 20 independent mocks of 6dFGSv within the GiggleZ volume. We show the mean and variance of the redshift distribution of our 20 mocks, compared with 6dFGSv, in Fig. 6. The mocks appear higher than the data in the highest redshift bins \((0.04 < z < 0.05)\), although this could possibly be attributed to cosmic variance. However, the large-scale bulk flow properties of
the mocks will not depend strongly on the exact shape of the redshift distributions, since the bulk flow depends to first order on the velocities of galaxies, not on their number density.

6 RESULTS AND DISCUSSION

We present in this section the bulk flow results of our 6dFGSv analysis, for the MV and MLE estimators, along with the bulk flow results for our ΛCDM mocks. We then compare our results to a theoretical ΛCDM prediction, first considering the 3D bulk flow amplitude, and secondly considering each of the three 1D bulk flow components, to obtain constraints on Ω_m and σ_8.

6.1 Bulk flow results

We have calculated the bulk flow for 6dFGSv for the two different bulk flow estimators described in Section 4.

(i) The MV estimate, using two different ideal surveys: (1) a Gaussian survey with effective radius \( R_1 = 50 h^{-1} \) Mpc; (2) a Gaussian survey of radius \( R_1 = 70 h^{-1} \) Mpc. To each ideal survey we apply a cut-off at 160 \( h^{-1} \) Mpc, the survey limit.

(ii) The MLE.

Our measurement represents an estimation of the bulk flow in the Southern hemisphere, out to 50–70 \( h^{-1} \) Mpc.

The results are presented in Table 1, in both Galactic Cartesian coordinates and equatorial Cartesian coordinates. We include the equatorial coordinates, since 6dFGSv covers only half the sky in equatorial coordinates, and equatorial Cartesian coordinates. We include the window functions, with angles in Galactic longitude (l) and latitude (b), while the lower panel shows equatorial coordinates, with angles in RA and Dec. The uncertainties quoted are noise, with the cosmic variance uncertainty in parentheses. The MV methods use an ideal Gaussian window function, with radius \( R_1 = 50 \) or \( 70 h^{-1} \) Mpc, and with a cut-off at 160 \( h^{-1} \) Mpc corresponding to the redshift cut-off of the survey.

![Figure 7](http://mnras.oxfordjournals.org/) The window functions \( \mathcal{W}_{ij}^2 \) (from equation 24) of the bulk flow components for 6dFGSv, for each of our three estimators: the MV estimate with \( R_1 = 50 \) or \( 70 h^{-1} \) Mpc, and the MLE method. The equatorial Cartesian x, y, z components are the solid green, dashed blue, solid red lines, respectively.

**Figure 7.** The window functions \( \mathcal{W}_{ij}^2 \) (from equation 24) of the bulk flow components for 6dFGSv, for each of our three estimators: the MV estimate with \( R_1 = 50 \) or \( 70 h^{-1} \) Mpc, and the MLE method. The equatorial Cartesian x, y, z components are the solid green, dashed blue, solid red lines, respectively.

**Table 1.** Bulk flow results for the MV and MLE estimators, assuming peculiar velocity uncertainties \( \sigma_v = 0.324H_0D_\gamma \) km s\(^{-1}\) for each galaxy. Columns are the bulk flow magnitudes \( |U| \), the vector components \( (u_x, u_y, u_z) \), and angular coordinates. The top panel shows Galactic coordinates, with angles in Galactic longitude (l) and latitude (b), while the lower panel shows equatorial coordinates, with angles in RA and Dec. The uncertainties quoted are noise, with the cosmic variance uncertainty in parentheses. The MV methods use an ideal Gaussian window function, with radius \( R_1 = 50 \) or \( 70 h^{-1} \) Mpc, and with a cut-off at 160 \( h^{-1} \) Mpc corresponding to the redshift cut-off of the survey.

| Bulk flow estimator | \( |U| \) (km s\(^{-1}\)) | \( u_x \) (km s\(^{-1}\)) | \( u_y \) (km s\(^{-1}\)) | \( u_z \) (km s\(^{-1}\)) | l/RA (°) | b/Dec. (°) |
|---------------------|------------------|--------------------|--------------------|--------------------|----------|-----------|
| Galactic coordinates | | | | | | |
| MV (\( R_1 = 50 h^{-1} \) Mpc) | 248 ± 58(100) | 142 ± 66(106) | -127 ± 72(114) | 159 ± 59(103) | 318 ± 20 | 40 ± 13 |
| MV (\( R_1 = 70 h^{-1} \) Mpc) | 243 ± 58(101) | 139 ± 66(106) | -125 ± 72(114) | 154 ± 59(102) | 318 ± 20 | 39 ± 13 |

| MLE | 295 ± 48(138) | -212 ± 46(114) | -125 ± 55(115) | 162 ± 53(186) | 211 ± 13 | 33 ± 10 |
Figure 8. The 6dFGSv bulk flow result in this work, compared with other bulk flow measurements and nearby superclusters. The figure shows Galactic longitude ($l$) and latitude ($b$), in an Aitoff projection. Our MV result for $R_l = 70 h^{-1}$ Mpc is shown as the black circle, while our MLE result is shown as the green circle (labelled). The diameter of the circles is proportional to the amplitude of the bulk flow, with inner and outer circles indicating the 1σ confidence interval of this amplitude. The error bars show the 1σ angular uncertainty. The cyan circles show the distribution of bulk flows measured in our 20 GiggleZ 6dFGSv mock catalogues. Again, the size of the circles corresponds to the bulk flow amplitude, and since these are from simulations they have no measurement uncertainties. Our result for $R_l = 50 h^{-1}$ Mpc is almost identical to the one for $70 h^{-1}$ Mpc. The 6dFGSv galaxies are shown in grey for reference. We show the directions of several other results from the literature by the solid blue circles: WFDH09 (W09); Dai et al. (2011) (D11); Nusser & Davis (2011) (N11); Turnbull et al. (2012) (T12); Lavaux et al. (2013) (L13); and Planck Collaboration XIII (2014) (P13). The four largest local superclusters are shown by the solid magenta circles: the Shapley Supercluster; Hydrus–Centaurus (HC); Horologium–Reticulum (HR); and Perseus–Pisces (PP). The South Celestial Pole (SCP) is also shown in magenta for reference. The CMB dipole is indicated by the red and blue stars (with red the direction of the dipole), and the direction of the LG motion (from Kogut et al. 1993) is shown by the black star.

function can give quite a large difference in the bulk flow, which is what we observe. What is important is how we compare the results with a theoretical model. The MV method is more straightforward to compare with theory, since it gives the bulk flow for a specified window function which we can include in the theoretical model.

We show the sky positions of our MV and MLE bulk flow measurements in Fig. 8. The CMB dipole is shown for comparison, along with a number of recent bulk flow measurements from the literature. We also show on this plot the position of the Shapley Supercluster ($l = 312^\circ$, $b = 31^\circ$). Our MV measurement is very close to the direction of Shapley, and consistent with it within the angular uncertainties. Unlike all sky peculiar velocity surveys, 6dFGSv will be dominated by southern sky structures, since the gradient of the velocity field towards these structures will be larger, and so it is not surprising that our measurement is close to Shapley. Also, the 6dFGSv number density of galaxies peaks beyond $100 h^{-1}$ Mpc, incorporating part of Shapley, so this survey selection criteria itself will likely cause the Shapley region to dominate our bulk flow results.

In this figure, we also show the bulk flow results from our 20 GiggleZ-based mock catalogues, which we will discuss further in Section 6.2.

### 6.2 6dFGSv bulk flow distribution in ΛCDM mocks

We use our N-body simulation-based mock catalogues to determine the expected distribution of bulk flows for 6dFGSv in a ΛCDM universe. We calculate the bulk flow amplitude in each of the 20 mocks, using the MV method with $R_l = 50 h^{-1}$ Mpc, and show their histogram in Fig. 9. We also show the corresponding bulk flow magnitude from the data, along with the 1σ noise uncertainty; this is above the average, but within the expected range of the mocks. Seven of the mocks, or 35 per cent, lie above our result, while 65 per cent lie below.

The direction and amplitude of the bulk flow measured in each of these mocks is shown in Fig. 8. This is a useful test to see whether the survey window function can bias the direction of the measured bulk flow. We see that the directions of the mocks appear fairly random and isotropic. There are more in the northern sky (13) than the southern sky (7), but this is not significant. It is also possible the mocks may share large-scale modes, since they all lie within the same Gpc volume, so it could be they are not completely independent.

### 6.3 Comparison with linear theory: 3D bulk flow

Since the bulk flow amplitude is sensitive to the large-scale modes of the matter power spectrum, the measured bulk flow can be
which depends on the rms velocity dispersion, $V$, where $P$ dispersion is given by

$$P(R) = \frac{H_0^2}{2\pi^2} \int_{k=0}^{\infty} dk P(k) \tilde{W}(k; R)^2.$$

The expected bulk flow velocity $V(R)$ can be predicted from $\sigma_V$, assuming the peculiar velocity field is Maxwellian, which will be if the density field is Gaussian random. For a Maxwellian distribution, the probability distribution function of the bulk flow amplitude $V$ is (Bahcall, Gramann & Cen 1994; Coles & Lucchin 2002)

$$p(V)dV = \sqrt{\frac{\sigma_V}{\pi \sigma_V}} \left( \frac{3}{\sigma_V} \right)^{3/2} V^2 \exp \left( -\frac{3V^2}{2\sigma_V^2} \right) dV.$$

For such a distribution the most likely (maximum likelihood) bulk flow amplitude is $V_{ML} = \sqrt{27/2} \sigma_V$, while the expectation value is $\langle V \rangle = 2V_{ML}/\sqrt{\pi} = \sqrt{8/\pi} \sigma_V$.

In Fig. 10 we plot $V_{ML}$ along with the upper and lower $1\sigma$ and $2\sigma$ confidence levels as the dark and light grey shaded regions, found from integrating equation (31). These confidence levels correspond to the variance ranges $V_{ML}-0.35\sigma_{ML}$ and $V_{ML}-0.89\sigma_{ML}$ ($1\sigma$) and $V_{ML}-0.89\sigma_{ML}$ and $V_{ML}+2\sigma_{ML}$ ($2\sigma$). To calculate $\sigma_V$, we use a $\Lambda$CDM matter power spectrum, generated using CAMB (Lewis, Challinor & Lasenby 2000) with non-linear evolution calculated using HALOFIT (Smith et al. 2003), and with the parameters listed in Section 1.

Caution is needed in interpreting this plot, since the different surveys have different window functions, and so cannot be directly compared, either with each other or with the theoretical prediction for a perfect all-sky Gaussian. A selection function tends to reduce the effective scale of a survey, which increases $\sigma_V$ and hence $V$ for that survey. However, simulations show that the PDFs of bulk flows depend primarily on $\sigma_V$, and not on the type of window function, and so assuming an effective radius for the window function used in the model (e.g. a Gaussian in our case) that reproduces the same $\sigma_V$ as the survey window function would allow a comparison at that scale (Li et al. 2012). We have not done this in this plot, and note that there is some uncertainty on the effective scale of the different surveys.

Since 6dFGSv only covers half the sky, we would expect our measurements at given radius $R_I$ to have more cosmic variance than predicted by the full-sky model at this radius. Conversely, we could consider 6dFGSv to be at a smaller effective radius. We therefore plot our 6dFGSv MV results at ‘effective radii’ $R_{eff}$ accounting for the fact that 6dFGSv covers only half the sky. For each of the $R_I = 50$ and $70 h^{-1}$ Mpc results, we calculate the radius of a full sphere with the same volume as the half-sky measurement, i.e.

$$R_{eff} = (R_I/2)^{3/2}.$$

This gives effective radii of $R_{eff} = (39.7, 55.6) h^{-1}$ Mpc for the $R_I = (50, 70) h^{-1}$ Mpc measurements. We plot arrows showing how we have shifted the measurements from $R_I$ to $R_{eff}$. However, since
6dFGSv is not a perfectly sampled hemisphere, we might expect the effective radii to be even smaller than the $R_{\text{eff}}$ we calculate.

From Fig. 10 we see that once shifted to the effective radii, both the 6dFGSv $R_i = 50$ and $70$ $h^{-1}$ Mpc bulk flow results appear to be consistent within 68.3 per cent confidence with the theoretical prediction.

The uncertainty on the effective radii of previous surveys may mean that those that showed higher than predicted bulk flows could have been compared to theory at too large a radius, without accounting for how the window function reduces the effective volume of the survey. It would be illuminating to recalculate the effective radii of these surveys to investigate this; we leave this for future work.

### 6.4 Comparison with linear theory: 1D bulk flow

Unlike the 3D bulk flow amplitude, the 1D bulk flow components $u_i$ are Gaussian distributed, making them more useful for a robust test of ΛCDM. The 1D rms velocity variance is given for a particular survey by the covariance matrix of the bulk flow moments, $R_{ij}$, which we defined in Section 4.3. It is the sum of a noise component and a cosmic variance component, and it depends on the survey geometry, the measurement noise, and the matter power spectrum. It is very similar to the rms velocity variance $\sigma_V$ in equation (30), except for the addition of the noise component, and the cosmic variance component $R^{(i)}_{ij}$ contains the tensor window function $\mathcal{W}_V(k)$. (We previously defined $\sigma_1$, as the 1D velocity variance; this is in principle the average variance over all scales, which we assumed to be equal to $\sim 250$ km s$^{-1}$. Here, however, we are looking at the variance as a function of scale.)

The deviation from zero of the observed bulk flow components $u_i$ can be directly compared with the predicted dispersion, by calculating the $\chi^2$ for the three moments:

$$\chi^2 = \sum_{i,j} u_i R^{-1}_{ij} u_j,$$

where $i$ and $j$ both go from 1 to 3 to specify the bulk flow components, $u_i$ and $u_j$ are the measured bulk flow components, and $R_0$ is the covariance matrix of the moments for a specified set of cosmological parameters.

$R_0$ is dominated by the cosmic variance term, typically of order $\sim 100$ km s$^{-1}$, while the noise term is typically $\sim 40$ km s$^{-1}$. Since the bulk flow depends on large-scale density fluctuations, $R_0$ will be most sensitive to the amplitude and shape of the power spectrum. The power spectrum amplitude is parametrised by the rms density fluctuations in spheres of $8 h^{-1}$ Mpc radius, $\sigma_8$, while the shape is parametrised by the shape parameter, $\Gamma$, which on large scales can be approximated by $\Gamma = \Omega_m h$. The dependence on $\Omega_m$ also comes into the $f(\Omega_m, z)^2$ factor. We therefore follow WFD09 in using the bulk flow to constrain a combination of $\Omega_m$ and $\sigma_8$ – in our case, we fix $h$ to the best-fitting value from Planck, $h = 0.67$.

In order to fit $\Omega_m$ and $\sigma_8$ we use the likelihood, following WFD09, which is given by

$$L(\Theta) \propto \frac{1}{\sqrt{|R|}} \exp \left( \sum_{i,j} -\frac{1}{2} u_i R^{-1}_{ij} u_j \right),$$

where $\Theta$ is the vector of parameters. In our case, $\Theta = (\Omega_m, \sigma_8)$, and we fix all other parameters to their Planck values.

We show our constraints on $\sigma_8$ and $\Omega_m$ for our MV results in Fig. 11. There is a degeneracy between $\sigma_8$ and $\Omega_m$, since a lower $\sigma_8$ requires a lower $\Omega_m$ to produce the same bulk flow; or, for fixed $\sigma_8$, lower values of $\Omega_m$ lead to a larger bulk flow. This is because if $\sigma_8$ is fixed, then a lower $\Omega_m$ requires a larger power spectrum amplitude on large scales to allow this normalisation. However, since a lower $\Omega_m$ also decreases the growth rate $f(\Omega_m, z)$, these two effects partially cancel, and so the bulk flow does not have much constraining power on $\Omega_m$. The Planck value is shown as the black point, and is within the 1$\sigma$ range of our measurement.

Marginalising over $\Omega_m$, we obtain the likelihood for $\sigma_8$. The results are shown in Fig. 12. Our results favour a high value of $\sigma_8$, but we do not find a significant disagreement with ΛCDM. For the MV $R_i = 50 h^{-1}$ Mpc measurement, we find $\sigma_8 = 1.03^{+1.08}_{-0.58}$ (68.27 per cent confidence level), and for $R_i = 70 h^{-1}$ Mpc, we find $\sigma_8 = 1.01^{+1.07}_{-0.55}$. Both of these are consistent with the Planck value of $0.83 \pm 0.03$ (Planck Collaboration XVI 2014).

and are shifted to the right for clarity. The black line shows the bulk flow

sky Gaussian window function with radius 50 or 70

0.01. The coloured lines show the equatorial (x, y, z) components (labelled)

and model power spectrum. Following WFH09, we list

window function and model power spectrum. Following WFH09,

we list

6dFGSv results for

R

50 h

Mpc. We would expect these to closely agree with the

window function of the data, and this is roughly true. The

changes in the MV bulk flow values we find, after adding or

subtracting 0.003 dex, are all smaller than the noise uncertainties

on our bulk flow measurement. Hence the statistical uncertainty on

the zero-point does not significantly affect our measurement.

There is also cosmic variance in the zero-point, i.e. in the net

velocity of galaxies within the ‘great circle’, −20° ≤ Dec. ≤ 0°. We

can estimate this using our ΛCDM mock catalogues, as follows.

(i) In each mock catalogue, calculate the mean radial component of peculiar velocity of galaxies within −20° ≤ Dec. ≤ 0°. We can estimate this using our ΛCDM mock catalogues, as follows.

(ii) Then subtract this mean radial velocity from all of the galaxies

in the mock.

(iii) Calculate the MLE bulk flow of the mock before and after doing this.

(iv) Calculate the vector difference between these.

We find the rms variance in the mean radial peculiar velocity in the

great circle, over all the mocks, is 82 km s

−1 (km s

1)( km s

−1 Mpc) (km s

1)( km s

1 Mpc) (km s

−1 Mpc). We would expect these to closely agree with the

window function of the data, and this is roughly true. The

last two rows of Table 2 show the analytic prediction for an all-sky Gaussian window function with radius 50 or 70 h

−1 Mpc, by evaluating equation (30) at these values of R.

Table 2. Comparison of the expected 1D rms velocity σ

V,i, and 3D rms velocity σ

V, for 6dFGSv, our GiggleZ-based 6dFGSv mocks, and for theory. We use equatorial Cartesian coordinates, and assume a ΛCDM cosmology with parameters listed in Section 1.

Notes. ^a σ_{V,i} = \sqrt{R_{ij}}, from equation (21), and \sigma_{V}^2 = I R_{ij} J^T, where J is the Jacobian. Includes both noise and cosmic variance.

^b All calculated from rms of bulk flow components of 20 mocks. Includes both noise and cosmic variance.

^c Calculated from equation (30). Includes noise only and assumes a full-sky window function.

The diagonal elements of R_i provide the expected 1D rms bulk

flow velocity variance \sigma_{V,i}^2 in each of the three directions i, for a given survey window function and model power spectrum. Following WFH09, we list \sigma_{V,i}^2 = \sqrt{R_{ii}} in Table 2 for 6dFGSv, for the MLE and MV estimators.

We also show in this table the 1D and 3D rms velocities calculated from our 20 GiggleZ-based mocks, using the MV estimator with

R_i = 50 h^{-1} Mpc. We would expect these to closely agree with the

6dFGSv results for R_i = 50 h^{-1} Mpc, since the mocks reproduce the window function of the data, and this is roughly true. The

last two rows of Table 2 show the analytic prediction for an all-sky Gaussian window function with radius 50 or 70 h^{-1} Mpc, by evaluating equation (30) at these values of R.

6.5 Bulk flow in redshift shells

It is interesting to look at how the bulk flow varies as a function of

redshift. In Fig. 13 we plot the MLE bulk flow, split into redshift

bins of Δz = 0.01. In each redshift bin, we recalculate the MLE

weights for only galaxies in that bin. The results are noisy, but the amplitude of the bulk flow seems to be fairly constant up to the

maximum redshift of z = 0.054. This is what would be expected if

the source of the bulk flow is an overdensity more distant than the

scales measured.

6.6 Zero-point uncertainty

So far our analysis has assumed a fixed zero-point for the FP. S14

fix the zero-point by assuming zero average radial peculiar velocity

in a ‘great circle’ around the equator, consisting of 3828 galaxies

with −20° ≤ Dec. ≤ 0°. (In practice they assume zero average

logarithmic distance ratio \eta.) However, this zero-point estimation has both statistical uncertainty and cosmic variance. We investigate

the effect of these on our bulk flow measurement here.

The statistical uncertainty on the zero-point was calculated by

S14 to be 0.003 dex. We test the effect of this uncertainty on our

bulk flow measurement, by repeating the analysis but first shifting

all the \eta values by +0.003 or −0.003 dex. This changes the derived peculiar velocities \nu, the estimated velocity uncertainties \sigma_{\nu} (see Section 3), and the resulting bulk flow. We list the new \sigma_{\nu} and MV bulk flow values in Table 3.

The changes in the MV bulk flow values we find, after adding or

subtracting 0.003 dex, are all smaller than the noise uncertainties

on our bulk flow measurement. Hence the statistical uncertainty on

the zero-point does not significantly affect our measurement.

Figure 13. The MLE bulk flow for 6dFGSv in redshift shells of width Δz = 0.01. The coloured lines show the equatorial (x, y, z) components (labelled) and are shifted to the right for clarity. The black line shows the bulk flow magnitude. The number of galaxies in each redshift shell is {75, 813, 1371, 2563, 2802, 1261}. The error bars indicate the noise uncertainty in each bin.

There is also cosmic variance in the zero-point, i.e. in the net

velocity of galaxies within the ‘great circle’, −20° ≤ Dec. ≤ 0°. We can estimate this using our ΛCDM mock catalogues, as follows.

(i) In each mock catalogue, calculate the mean radial component of peculiar velocity of galaxies within −20° ≤ Dec. ≤ 0°. We can estimate this using our ΛCDM mock catalogues, as follows.

(ii) Then subtract this mean radial velocity from all of the galaxies

in the mock.

(iii) Calculate the MLE bulk flow of the mock before and after doing this.

(iv) Calculate the vector difference between these.

We find the rms variance in the mean radial peculiar velocity in the

great circle, over all the mocks, is 82 km s

−1 and the rms variance in logarithmic distance ratio \eta is 0.004 dex. The rms variance in the vector shift in bulk flow, over all the mocks, is (\delta_u, \delta_v, \delta_w) ≡ (3, 8, 128) km s

−1 in equatorial Cartesian coordinates, shown in Table 4. In other words, the zero-point calibration induces a rms variance primarily in the north–south direction.

We note that if the net radial peculiar velocity in the ‘great circle’ is negative, i.e. towards the observer, then calibrating it to zero shifts the measured bulk flow to more negative Dec. If the net velocity is

positive, then the shift is towards more positive Dec. Either way, there is negligible shift in RA, since 6dFGSv is fairly symmetrical in equatorial $x$ and $y$.

The cosmic variance this adds to our 6dFGSv bulk flow measurement depends on the direction and amplitude of the measurement. We show the resulting cosmic variance on the amplitude and direction of our MV bulk flow measurements at $R_l = 50$ and $70 \, h^{-1} \text{ Mpc}$ in Table 4. The uncertainty on the bulk flow amplitude due to cosmic variance in the zero-point is $\sim 50 \, \text{km s}^{-1}$, slightly smaller than the statistical uncertainty of $58 \, \text{km s}^{-1}$.

6.7 Comparison with other results

We compare our bulk flow result to other recent measurements in the literature, in Table 5. Our result is one of the most precise to date, thanks to the large number of galaxies in 6dFGSv. Our MV result of $248 \pm 58 \, \text{km s}^{-1}$ at $R_l = 50 \, h^{-1} \text{ Mpc}$ is a significantly lower amplitude than that of WFH09 at the same scale, despite the fact that the 6dFGSv survey volume is smaller than the COMPOSITE sample that they use, and so might be expected to have more cosmological variance. The level of disagreement between our result and WFH09, not accounting for this volume difference, is 1.56σ.

Our result is consistent with a growing number of recent measurements that find a bulk flow amplitude consistent with ΛCDM, including Colin et al. (2011), Dai et al. (2011), Nusser & Davis (2011), Turnbull et al. (2012), Feindt et al. (2013), and Carrick et al. (2015).

As we see in Table 5 and Fig. 8, the direction of our bulk flow is much closer to Shapley than other bulk flow measurements. This is reasonable, since 6dFGSv covers only the Southern hemisphere, and so the bulk flow we measure is likely to be dominated by large southern structures such as Shapley.

We note again that the different surveys quoted in this table all have different window functions, so even those at the same effective distance may not be directly comparable. In particular a region of a ‘quiet’ Hubble flow has been identified in the northern sky (Courteau et al. 1993) which is in contrast to the southern sky that has large motions arising from the Great Attractor and the Shapley Supercluster (see e.g. Hudson et al. 1999; Feindt et al. 2013). If the Turnbull et al. (2012) Type Ia supernova data set is subdivided into north and south samples, the measured bulk flow amplitudes are $110 \pm 90$ and $320 \pm 120 \, \text{km s}^{-1}$, respectively. As data sets improve such biases will need to be fully addressed.

As a final point, recently Johnson et al. (2014) measured the velocity power spectrum of the 6dFGSv data set as a function of scale, and found it to be 1σ larger than the prediction given by a Planck cosmology on the largest scale they measured ($k = 0.005, 0.021$). However, they find it to be consistent at the 2σ level. This is consistent with our fit to $\Omega_m$ and $\sigma_8$ in Fig. 11, which is also consistent with Planck at the 1σ level. As Johnson et al. (2014) mention, this is not a significant disagreement with ΛCDM.

6.8 Implications for cosmography

An important aim for bulk flow measurements has been to understand the motion of the LG with respect to the CMB, of $627 \pm 22 \, \text{km s}^{-1}$ towards $l = 276^\circ \pm 3, b = 30^\circ \pm 2$ (Kogut et al. 1993). From gravitational instability theory, this is expected to be caused by nearby structures, and to converge to the CMB dipole beyond them.

As we showed in Fig. 8, the direction of our bulk flow is consistent with the direction of the Shapley Supercluster. We also saw in Fig. 13 that the amplitude of the bulk flow remains fairly constant with distance, indicating that it is sourced by a distant rather than a nearby overdensity. This therefore seems to indicate that Shapley may be the dominant source of the bulk flow motion we detect. Shapley is at a distance of $152 \, h^{-1} \text{ Mpc}$, is at a distance of $152 \, h^{-1} \text{ Mpc}$, and is the largest supercluster in the local Universe out to $200 \, h^{-1} \text{ Mpc}$ (Lavaux & Hudson 2011). Our result is consistent with many other bulk flow measurements that find directions close to Shapley (e.g. Feindt et al. 2013) and a
source distance greater than \(\sim 50–80 \, h^{-1} \text{Mpc}\) as the origin of the flow (e.g. Hudson 1994; Kocevski, Mullis & Ebeling 2004; Pike & Hudson 2005; WFH09).

Lavaux & Hudson (2011) calculate, using linear theory applied to 6dFGS redshift data, that Shapley should be responsible for \(\sim 15\%\) of the total velocity of the LG with respect to the CMB, or \(90 \pm 10 \, \text{km} \, \text{s}^{-1}\), while the Horologium–Reticulum supercluster generates \(\sim 60 \, \text{km} \, \text{s}^{-1}\). However, it appears that our sample is dominated mostly by Shapley. This makes it possible that its mass could be even larger than inferred from redshift data alone, which would agree with the finding of Feindt et al. (2013), who find that the bulk flow does not appear to reverse beyond Shapley, suggesting there could be more mass beyond it sourcing the bulk flow. They calculate that their bulk flow would be caused either if the mass of Shapley were twice as large as current estimates (from Muñoz & Loeb 2008; Sheth & Diaferio 2011), or if there were a more distant mass behind Shapley.

As we have previously noted, however, 6dFGSv partially samples the Shapley region, with no sampling at all of northern sky structures, so this could be partially responsible for Shapley dominating our results. Additionally, S14 show that the 6dFGSv sample shows not only an excess of positive velocities towards Shapley, but also an excess of negative velocities on the other side of the sky towards the Cetus Supercluster, compared to model predictions, indicating other structures are also contributing to the velocity dipole of the sample. As we found in Section 6.6, the cosmic variance in the zero-point of the FP also gives additional angular uncertainty to our measurement in the north–south direction. More analysis would therefore be needed to confirm whether the bulk flow is truly closer to Shapley than any other structure.

### 7 CONCLUSION

The question of whether a large bulk flow exists in the local Universe remains of much interest. A large part of the disagreement between previous measurements is likely due to the noisy, sparse peculiar velocity samples to date, as well as possible unknown systems such as differently calibrated data sets and Malmquist (or selection) biases. In this paper we aimed to make an improved measurement using a large new peculiar velocity data set, the 6dFGSv. This sample is homogeneously selected, so avoids any bias from combining data sets, and the uncertainties and Malmquist biases have been carefully studied and accounted for (M12; S14).

We have presented a new bulk flow analysis using this data set. Using the MV bulk flow estimator, we find a bulk flow of magnitude \(|U| = 248 \pm 58 \, \text{km} \, \text{s}^{-1}\) in the direction \((l, b) = (318^{\circ} \pm 20^{\circ}, 40^{\circ} \pm 13^{\circ})\) at a distance of \(50 \, h^{-1} \text{Mpc}\), and \(|U| = 243 \pm 58 \, \text{km} \, \text{s}^{-1}\) in the direction \((l, b) = (318^{\circ} \pm 20^{\circ}, 39^{\circ} \pm 13^{\circ})\) at a distance of \(70 \, h^{-1} \text{Mpc}\). This is somewhat higher than the \(\Lambda CDM\) prediction on these scales, implying a high value of \(\sigma_8\), but consistent with Planck results within 2\(\sigma\). After marginalizing over \(\Omega_m\), we find from our bulk flow measurement at \(R = 70 \, h^{-1} \text{Mpc}\) a value of \(\sigma_8 = 1.01^{+0.17}_{-0.28}\), consistent with the Planck value of 0.83 within 68.27 per cent confidence.

Our result is in agreement with a number of recent measurements that also find a bulk flow consistent with \(\Lambda CDM\), including Turnbull et al. (2012), Feindt et al. (2013), and Hong et al. (2014). Our result is also supported by the higher redshift measurement of Planck Collaboration XIII (2014), who used Planck CMB data combined with a large X-ray cluster catalogue, and found no evidence for a bulk flow from \(350 \, h^{-1} \text{Mpc}\) to \(2 \, h^{-1} \text{Gpc}\) scales.
A challenge for the 6dFGSv analysis here (and for any peculiar velocity analysis made using linear velocities instead of log distances) is accounting for the lognormal uncertainties on the peculiar velocities. When combined with the fact that 6dFGSv only covers half the sky, these can result in a spurious polar bulk flow component if not properly accounted for. We have shown that it is important to propagate uncertainty from the Gaussian observable (in our case, the logarithmic distance ratio $\eta = \log_{10}D_{z}/D_{r}$) to the non-Gaussian velocity in a way that is independent of the $\eta \rightarrow v$ conversion itself, so that the velocity uncertainties, and hence bulk flow weights, do not correlate with the velocities. A further effect may come from the fact that the distribution of measured velocities themselves will be affected by the lognormal uncertainties. A possible solution to this problem was recently suggested by Watkins & Feldman (2015). We leave investigation of this for 6dFGSv to future work.

Our measured bulk flow is very close to the direction of the Shapley Supercluster, consistent with many other measurements, and its amplitude appears to be fairly constant out to the distance of Shapley. This suggests that a large part of the bulk flow we measure is likely to be sourced by Shapley, which is reasonable since 6dFGSv is a southern sky survey.

Finally, we have also generated a set of ΛCDM mock catalogues of 6dFGSv, based on the GiggleZ N-body simulation and incorporating the 6dFGSv selection function, to be used for testing systematic biases in the data set. We find the 6dFGSv bulk flow amplitude is consistent with the distribution measured in the mocks. Using the mocks, we also estimate the additional uncertainty in our bulk flow amplitude, due to cosmic variance in the FP zero-point, to be $\sim 50 \text{ km s}^{-1}$.

These mocks are available on request for further analyses of the 6dFGSv sample. The C++ code written to calculate the MV bulk flow for this paper is publicly available on GitHub, at https://github.com/mscrim/MVBulkFlow.

ACKNOWLEDGEMENTS

We thank Hume Feldman and Richard Watkins for assistance with the MV implementation, and we also thank Hume and Pirin Erdogdu for helpful comments on this draft. Thanks also to Matt George and Jon Carrick for helpful discussions.

MIS acknowledges financial support from a Jean Rogerson Scholarship, a UWA Top-up Scholarship from the University of Western Australia, and a CSIRO Malcolm McIntosh Lecture bankmecu scholarship. MIS thanks the Astronomical Society of Australia for providing financial support via a Student Travel Award, which enabled furthered collaboration on this paper, and also Lawrence Berkeley National Laboratory for hosting her during part of this work. CB and TMD acknowledge the support of the Australian Research Council through the award of Future Fellowships, grants FT110100639 and FT100100595, respectively. The Centre for All-sky Astrophysics is an Australian Research Council Centre of Excellence, funded by grant CE110001020.

We define the matrices \( w_{i,n} \) as the set of weights which can be calculated for a given power spectrum. In linear theory between the bulk flow moments measured by the survey, \( U_{i} \), bulk flow moments that would be measured by an ‘ideal’ survey, \( U_{i}^{\prime} \). The authors implement the set of constraints in equation (A1) using Lagrange multipliers, and so the quantity to be minimized is

\[
\langle U_{i} - U_{i}^{\prime} \rangle + \sum_{j} \lambda_{ij} \left[ \sum_{n} w_{i,n} g_{j}(r_{n}) - \delta_{ij} \right].
\]

\[\text{(A3)}\]

Feldman et al. (2010) show that the weights can be evaluated as

\[
 w_{i,n} = \sum_{m} G_{nm}^{-1} \left( q_{nm} - \frac{1}{2} \sum_{j} \lambda_{ij} g_{j}(r_{m}) \right). \]

\[\text{(A4)}\]

We define the matrices \( G \), \( Q \), and \( \lambda \) below.

### A1 Velocity covariance matrix, \( G \)

\( G_{nm} = \langle s_{n}s_{m} \rangle \) is the covariance matrix for the individual velocities, which can be calculated for a given power spectrum. In linear theory it can be written in terms of the velocity field \( v(r) \) as

\[
 G_{nm} = \langle s_{n}s_{m} \rangle = \langle v_{n}v_{m} \rangle + \delta_{nm}(\sigma_{n}^{2} + \sigma_{m}^{2}).
\]

\[\text{(A5)}\]

The first, ‘geometrical’ term can be expressed as an integral over the density power spectrum \( P(k) \):

\[
 \langle v_{n}v_{m} \rangle = \frac{f(Q_{nm})^{2}H_{0}^{2}a^{2}}{2\pi^{2}} \int dk \, P(k) f_{nm}(k),
\]

\[\text{(A6)}\]

where \( H_{0} \) is the Hubble constant in units of \((\text{km} \, \text{s}^{-1} \, \text{Mpc}^{-1}) \), \( a \) is the cosmological scale factor, essentially equal to unity for the low redshifts we are considering, and the function \( f_{nm}(k) \) is the angle averaged window function,

\[
 f_{nm}(k) = \frac{1}{4\pi} \int d\delta \hat{k} \cdot (\hat{r}_{n} - \hat{r}_{m}).
\]

\[\text{(A7)}\]

This equation can be calculated analytically, as shown in the appendix of Ma et al. (2011).

### A2 Velocity bulk flow cross-correlation, \( Q \)

The correlation matrix \( Q_{nm} \) is calculated in a similar way, but incorporates the window function of the input ‘ideal’ survey. It is evaluated by generating an ideal survey with \( N \) random positions \( r_{i} \) with the desired radial distribution function. \( Q_{nm} \) is then given by

\[
 Q_{nm} = \langle U_{i}v_{n} \rangle = \sum_{n'=1}^{N} w_{i,n'}^{\prime}(v_{n'}v_{n}).
\]

\[\text{(A8)}\]

The weights \( w_{i,n'}^{\prime} \) for the ideal survey simply give the bulk flow as the average of the projections of the radial velocities on the three coordinate axis directions:

\[
 w_{i,n'}^{\prime} = \frac{3\hat{r}_{i} \cdot \hat{r}_{n}}{N}.
\]

\[\text{(A9)}\]

(Note in WFH09 the factor of 3 has been omitted from this equation.) Following WFH09 we create an ‘ideal’ survey with \( N = 10^{6} \) and a Gaussian radial density function \( n(r) \propto \exp(-r^{2}/2R_{Q}^{2}) \), where \( R_{Q} \) is the effective radius of the Gaussian.

Then, we evaluate \( \langle v_{n}v_{m} \rangle \) by

\[
 \langle v_{n}v_{m} \rangle = \frac{f(Q_{nm})^{2}H_{0}^{2}a^{2}}{2\pi^{2}} \int dk \, P(k) f_{nm}(k).
\]

\[\text{(A10)}\]

### A3 Lagrange multiplier, \( \lambda \)

The Lagrange multiplier \( \lambda_{ij} \) is given by

\[
 \lambda_{ij} = \sum_{l=1}^{3} \left[ M_{ij}^{-1} \left( \sum_{n,m} G_{nm}^{-1} \langle q_{lm}(r_{n}) \hat{r}_{j}(r_{m}) \rangle - \delta_{ij} \right) \right].
\]

\[\text{(A11)}\]

where

\[
 M_{ij} = \frac{1}{2} \sum_{n,m} G_{nm}^{-1} g_{j}(r_{n})g_{j}(r_{m}).
\]

\[\text{(A12)}\]

For the bulk flow, with \( g_{j}(r) = \hat{r}_{j} \), the latter equation becomes

\[
 M_{ij} = \frac{1}{2} \sum_{n,m} G_{nm}^{-1} \langle \hat{r}_{i}(r) \hat{r}_{j}(m) \rangle.
\]

\[\text{(A13)}\]
