1. INTRODUCTION

Relatively warm ($>1^{\circ}\text{C}$), nutrient rich and CO_2 saturated upper circumpolar deep water (UCDW) is transported around the Antarctic continent in the Antarctic Circumpolar Current, which is in turn driven by the Southern Hemisphere Westerly Winds (SWW). Where the Antarctic Circumpolar Current flows close to the Antarctic continental shelf edge, along the West Antarctic Peninsula (WAP), Bellingshausen and Amundsen Seas, upwelled-UCDW frequently spills onto the shelf via bathymetric troughs, circulating relatively warm water under ice shelves and contributing to their retreat (Jacobs et al., 2011; Jenkins and Jacobs, 2008; Wåhlin et al., 2010; Walker et al., 2007). More frequent and/or stronger incursions of UCDW are believed to contribute to recent, rapid warming (Vaughan et al., 2003), accelerated ice sheet thinning (Pritchard et al., 2012), reduced sea ice extent and notable changes in phytoplankton communities (Montes-Hugo et al., 2009) along the WAP in recent decades (Ducklow et al., 2012). The rapid deglacial retreat of the Marguerite Bay ice stream from ~ 9.6 kyr BP, is widely considered to have been driven by enhanced incursions of warm UCDW encroaching onto the WAP continental shelf (Bentley et al., 2011; Kilfeather et al., 2011). While predicted intensification of the SWW in coming years (Swart and Fyfe, 2012) may continue to promote UCDW upwelling and further threaten WAP ice shelf stability, a consensus on how UCDW along the WAP responded to changing SWW in the past has yet to be achieved (Ishman and Sperling, 2002; Shevenell and Kennett, 2002; also see discussion in Bentley et al., 2009). The aim of this paper was to assess the sensitivity of UCDW upwelling along the WAP to past changes in SWW by analysing the exceptionally well preserved planktonic and benthic foraminifera, diatoms and pigments in marine sediment core TPC522, Marguerite Bay (Fig. 1). These biogenic components provide proxies for reconstructing past surface and bottom water conditions and documenting the changing influence of UCDW on

1 the inner WAP continental shelf. We compare these reconstructions with other Southern
2 Hemisphere records to infer the sensitivity of UCDW-upwelling to SWW intensity and
3 position and the impact of UCDW-upwelling on deglaciation.

4

5 **1.1. Regional setting**

6 Piston core TPC522, collected on British Antarctic Survey cruise JR179 in 2008 recovered
7 11.7 m of sediment from inner Marguerite Bay (67° 51'.33 S 68° 12'.28 W; Fig. 1). The site
8 of TPC522, in 910 m of water, is downstream of Marguerite Trough which funnels UCDW
9 directly from the continental shelf edge, where the Antarctic Circumpolar Current spills into
10 bathymetric lows (Klinck et al., 2004; Martinson et al., 2008; Moffat et al., 2009). These
11 incursions of UCDW are modified and cooled through mixing with overlying relatively cold
12 and fresh Antarctic Surface Water (AASW) such that modified UCDW floods the continental
13 shelf to the base of the pycnocline (Martinson et al., 2008; Fig.2A). The presence of UCDW
14 beneath the pycnocline on the WAP is identified by temperature and salinity maxima as well
15 as oxygen minima (Klinck et al., 2004). Being enriched in nutrients and remineralised
16 organic matter, UCDW is also depleted in ^{13}C and has diagnostic benthic $\delta^{13}\text{C}$ values $<0.4\text{‰}$
17 (Mackenesen, 2012). Deep mixing of the AASW occurs during the winter months when
18 UCDW-derived heat and nutrients may be incorporated into surface waters (Smith et al.,
19 1999; Prezelin et al., 2000). Subsequent stratification during the summer months as
20 temperatures rise and ice melts is associated with intense primary productivity (e.g. Prezelin
21 et al., 2000) and the occurrence of a remnant Winter Water temperature minimum at 50-150
22 m water depth (Meredith et al., 2013; see Fig. 2A). Mixing of UCDW within surface waters
23 is therefore recognised by enhanced primary productivity (Prezelin et al., 2000) and reduced
24 sea ice extent (Martinson et al., 2008).

2. METHODS

The chronology of TPC522 is based on twelve acid insoluble organic matter (AIOM), and one monospecific benthic foraminifera (*Globocassidulina bitora*) radiocarbon dates. Dates were calibrated using CALIB 6.0 using the MARINE09 calibration curve (Stuiver & Reimer, 1993). ΔR was set at 1353 years based on a local mean surface sample radiocarbon age of 1753 ^{14}C yr BP from box cores BC523 (at the site of TPC522) and BC521 (9.2 km distant) minus the global ocean reservoir correction of 400 years. Dates are reported as conventional radiocarbon years BP (^{14}C yr BP) $\pm 1\sigma$ and in calibrated years BP (cal yr BP relative to AD 1950; Table 1). Classical radiocarbon age-depth modelling was undertaken using CLAM v, 2.1 software in R (Blaauw, 2010) using a smooth spline curve fit, running 1000 iterations at 1 cm intervals (Fig. 3A). To independently date the surface sediments, excess ^{210}Pb activity was measured on thirteen downcore samples in the top 23 cm of BC523 using a J- shaped ultra low background germanium well detection system at Durham University. Data analysis and dating model calculations were undertaken following the standard procedures defined in Appleby (2001).

For foraminifera and ice rafted debris (IRD) analysis, samples of $\sim 2\text{ cm}^3$ were collected at up to 5 cm intervals, then weighed and sieved through a 63 μm mesh using de-ionised water. The residues were dried at 45 $^\circ\text{C}$. Separate samples were collected every 10 cm for wet and dry weight and bulk density measurements without risking the integrity of the foraminiferal geochemistry. Dried samples from 10 to 20 cm intervals were sieved through a 125 μm sieve. Samples with abundant foraminifera were split with a microsplitter prior to sieving. At least 100 specimens of benthic foraminifera were counted per sample wherever possible. Between 5 and 20 specimens of *N. pachyderma* sin. and *B. aculeata* were picked from each sample wherever possible for stable isotope analysis. Stable isotope analyses were

1 carried out using a VG PRISM mass spectrometer at the Godwin Laboratory, Cambridge and
2 were measured relative to the Vienna Peedee Belemnite (VPDB) with reproducibility
3 <0.08 ‰ for $\delta^{18}\text{O}$ and <0.06 ‰ for $\delta^{13}\text{C}$. The concentration of glacial debris was determined
4 from counts of terrigenous grains from the >150 μm size fraction.

5 For diatom counts the quantitative slide preparation method of Scherer (1994) was
6 used and counting was carried out at $\times 1000$ magnification on an Olympus BX42 microscope.
7 Taxonomy followed Tomas (1997), supplemented by Fenner et al. (1976) and Johansen and
8 Fryxell (1985). To extract the most detailed environmental information from the diatom
9 record, species morphotypes *Thalassiosira antarctica* T1 and T2 (cold and warm varieties,
10 respectively; Buffen et al., 2007) and *Eucampia antarctica* var. *antartica* and var. *recta*
11 (symmetrical and asymmetrical forms respectively) were counted separately (Leventer et al.,
12 2002; Allen, 2014). *Chaetoceros* resting spores (CRS) comprise at least 82 % of the diatom
13 assemblage throughout TPC522. In order to extract the ecological information from the
14 minor species assemblages, CRS-free counts are presented based on minimum counts of 400
15 valves (excluding CRS) per slide. For statistical analyses, only diatom species that accounted
16 for >2 % of the CRS-free assemblage within at least one sample were included.
17 Correspondence analysis (CA) was performed on both the diatom and benthic foraminiferal
18 assemblage counts using the software of Hammer et al. (2005).

19 For pigment analysis, bulk sediment samples were freeze-dried and homogenised.
20 Approximately 2 g of sample was extracted with an organic solvent mixture of
21 dichloromethane/methanol (DCM/MeOH, 3:1, v/v), using a microwave assisted extraction
22 (Kornilova and Rosell-Mele, 2003). The temperature of the microwave was increased up to
23 70 °C over 2 minutes, held at 70 °C for 5 min and then allowed to cool. Extracts were
24 transferred to test tubes, centrifuged, and the supernatant dried by rotary evaporation.
25 Samples were redissolved in a known volume of acetone and transferred to a 2 ml quartz

1 cuvette for analysis in a WPA spectrophotometer. Absorbance was recorded by
2 measurements in triplicate at the wavelengths 410 nm and 665 nm, which correspond to the
3 diagenetic transformation products of chlorophyll, the chlorins (Harris et al., 1996).

4

5 **3. RESULTS**

6 **3.1 AGE-DEPTH MODEL**

7 The excess ^{210}Pb activity profile confirmed that the upper sediments were deposited
8 within recent decades (Fig. 3B). The surface sediment radiocarbon ages are therefore
9 considered a reliable indication of the modern ^{14}C reservoir age at this site, although older
10 reservoir ages have been reported in this region (Kilfeather et al., 2011; Graham & Smith,
11 2012). Total organic carbon values were relatively consistent downcore (0.9-1.7 %) and mean
12 $\delta^{13}\text{C}_{\text{AIOM}}$ was -21.6 ‰ with a standard deviation of 0.8 ‰ indicating that AIOM used for
13 radiocarbon dating was consistently of marine origin with no evidence of variable terrestrial
14 input. The AIOM age at 955 cm and benthic foraminifera sample at 1000 cm have
15 overlapping calibrated age ranges suggesting that the radiocarbon reservoir in the AIOM may
16 be slightly larger towards the base of the core (see Rosenheim et al., 2013). We considered
17 the conventional radiocarbon age 6420 ± 40 at 350 cm an unrealistic age-reversal and omitted
18 it from our age-depth model, although the $\delta^{13}\text{C}_{\text{AIOM}}$ does not suggest it was of a different
19 origin. The radiocarbon date at the top of PC522 (0-2 cm) gives a calibrated and corrected
20 age of 292-461 years suggesting the piston corer may have slightly over-penetrated the
21 surface.

22

23 **3.2 STATISTICAL ANALYSIS OF ASSEMBLAGES**

24 The first three axes of the CA accounted for 57% and 66% of the variance in the
25 diatom and foraminifera assemblages respectively (Fig. 4). Significant assemblage shifts (> 1

1 s.d.) were used to identify three stratigraphic intervals that approximately corresponding to
2 the early, mid and late Holocene. Boundaries between these stratigraphic intervals are at near
3 identical depths in the diatom and benthic foraminiferal records suggesting a close coupling
4 of surface and benthic conditions within inner Marguerite Bay. The early Holocene interval
5 begins at 9707 yr BP (best fit from the CLAM age-depth model with 95 % confidence levels
6 for these dates being 9618-9835 yr BP). Based on diatom assemblage change the early
7 Holocene interval extends to 6903 yr BP (95% confidence levels for this date being 6820-
8 6984 yr BP) and the benthic foraminifera assemblage change at 6992 yr BP (95% confidence
9 levels being 6907-7070 yr BP). The mid Holocene interval ends at 4213 yr BP based on the
10 diatom assemblage (with 95% confidence levels for this date being 4066-4341 yr BP) and
11 4153 yr BP based on the benthic foraminifera assemblage (with 95% confidence levels being
12 4008-4274 yr BP). From hereon in the single best fit date from the CLAM age-depth model
13 will be given.

14

15 **3.3 DIATOM ASSEMBLAGES**

16 Interpretations of the diatom and foraminifera assemblages were based on the auto-ecological
17 data presented in supplementary Table 1. The early Holocene diatom assemblage (9707 to
18 6992 yr BP), characterised by *Thalassiosira tumida*, *Eucampia antarctica* (Fig. 5F),
19 *Thalassiosira gracilis* and *Proboscia truncata*, is indicative of relatively warm surface
20 waters with a long growth season, minor sea ice influence and rich in iron; most likely
21 associated with seasonal glacial melt and late summer/autumn productivity (Stickley et al.,
22 2006; Allen et al., 2010). The high ratio of asymmetrical:symmetrical morphotypes of *E.*
23 *antarctica* (Fig. 5G) is consistent with relatively high sea surface temperatures (SST;
24 Leventer et al., 2002). *F. kerguelensis* is an open ocean species, used as a tracer for Antarctic
25 Circumpolar Current waters entrained onto the continental shelf (Bathmann et al., 1991;

1 Allen et al., 2010) or carried beyond the Southern Ocean (Stickley et al., 2001; Romero and
2 Hensen, 2002). Therefore the high relative abundance of open-water *F. kerguelensis* (Fig.
3 5D), within TPC522 suggests that the site was bathed by UCDW in the early Holocene. In the
4 mid Holocene (6903 to 4213 yr BP) the diatom assemblage shows a decline *E. antarctica* and
5 increases in *Thalassiosira antarctica* (cold morphotype; Fig. 5E) and *P. truncata*. This shift
6 in assemblage is interpreted as an increasing marginal sea ice influence, including the
7 presence of ice during the summer months (Pike et al., 2009), and a shortening of the growth
8 season. The persistent occurrence of *F. kerguelensis* during the mid Holocene interval
9 suggests that UCDW continued to bathe our site. The ratio of asymmetrical:symmetrical
10 morphotypes of *E. antarctica* peaks between 6903 and 5882 yr BP suggesting the warmest
11 SSTs of our record, before falling through the mid to late Holocene. The late Holocene
12 diatom assemblage (from 4213 yr BP) is marked by a very low abundance of the high
13 nutrient, warm, open-water assemblages of the early Holocene (i.e. *T. tumida*, *E. antarctica*,
14 and *F. kerguelensis*) and instead is characterised by sea ice proximal species (*Fragilariopsis*
15 *curta*, *Fragilariopsis cylindrus* and Parmales (Zielinski, 1997). This transition from the mid
16 to late Holocene assemblages is also marked by a prominent peak in the flux of diatoms
17 accumulation at the sea floor suggesting a brief interval of exceptionally high primary
18 productivity. Relatively high fluxes of diatoms continue to 2584 yr BP. The late Holocene
19 diatom assemblage reflects a significant sea ice influence and further shortening of the
20 growth season and declining productivity (diatom flux).

21

22 **3.4 BENTHIC FORAMINIFERAL ASSEMBLAGES**

23 Extensive dissolution of calcareous foraminifera can occur in sediments collected from the
24 WAP (Osterman et al., 2001). However, since the concentration of benthic foraminifera in
25 TPC522 exceeds that within ODP Site 1098 by orders of magnitude throughout the Holocene

1 (Supplementary Fig. 1) we consider dissolution to be less of an issue at TPC522 site compared
2 to Palmer Deep. SEM images from numerous depths are also provided (supplementary plates
3 1 and 2).

4 The early Holocene benthic foraminiferal assemblage (9707 to 6992 yr BP) is largely
5 comprised of *Fursenkoina fusiformis* and *Nonionella* spp. (Fig. 5K, L). These species are
6 commonly associated with sites subject to intense pulses of phytodetritus (Gooday, 2003;
7 Gooday et al. 2012) and organic-rich, low-oxygen settings (Sen Gupta and Machain-Castillo,
8 1993; Ishman and Domack, 1994). Along the WAP these species occur in surface sediment
9 samples of the Bransfield Strait (Ishman and Domack, 1994) and the Weddell Sea shelf
10 (Mackensen et al., 1990), where there is high productivity and high particulate organic carbon
11 export (Mackensen et al., 1990). Although it has been suggested that the modern
12 *Fursenkoina/Nonionella* assemblage in the Bransfield Strait is primarily indicative of
13 Weddell Sea Water (Ishman and Domack, 1994), the interpretations of Ishman and Sperling
14 (2002) and Kilfeather et al. (2011), that assemblages with high proportions of these species
15 are most likely tracking high productivity and organic carbon flux to the sea floor, is more
16 consistent with our other proxy data (see later discussion). In addition, Weddell Sea Water is
17 not known to reach this far south along the WAP (Martinson et al., 2008). The mid Holocene
18 foraminiferal assemblage (6992 to 4153 yr BP) is dominated by *Bulimina aculeata* (Fig. 5N).
19 *B. aculeata*, is associated organic-rich sediments (Mackensen et al. 1993) and has been used
20 as an UCDW tracer (Ishman and Domack, 1994) at Palmer Deep (Ishman & Sperling 2002)
21 and Lützow-Holm Bay (Igarashi et al. 2001). The late Holocene foraminiferal assemblage
22 (from 4153 kyr BP) oscillates between the *B. aculeata* assemblage of the mid Holocene and
23 predominantly agglutinated species (Fig. 5M). The agglutinated assemblage, dominated by
24 *Miliamina arenacea* and including *Trochammina* spp. and *Reophax* spp., is typical of the
25 agglutinated assemblages which characterise cold saline shelf water around Antarctica

1 (Ishman & Domack, 1994; Ishman & Sperling, 2002; Anderson, 1975; Milam & Anderson
2 1981; Majewski & Anderson, 2009). The oscillation between these two foraminiferal
3 assemblages suggests switching between two oceanographic modes; most likely the presence
4 of UCDW associated with the *B. aculeata* assemblage, and the presence of cold, saline shelf
5 water associated with the *M. arenacea* assemblage (Ishman & Sperling, 2002). These
6 assemblage oscillations are evident on a decadal to centennial timescale through the high
7 sedimentation up to 2679 yr BP and inferred to have persisted throughout the remainder of
8 the record but compromised by low sedimentation rates (<1 mm yr⁻¹ from 2679 yr BP)
9 which may have caused the signal to become homogenised.

10

11 3.5 STABLE ISOTOPES

12 Since foraminifera do not necessarily precipitate their carbonate in equilibrium with
13 seawater $\delta^{18}\text{O}_{\text{seawater}}$ we compared our records with predicted $\delta^{18}\text{O}_{\text{CaCO}_3}$ values to establish
14 whether it was necessary to apply a vital effect correction to either of the measured species.
15 Predicted $\delta^{18}\text{O}_{\text{CaCO}_3}$ for the entire water column was calculated from modern temperature and
16 salinity data (JR179 cruise CTD025 collected 2nd April 2008, see Fig. 1 for locality and Fig.
17 2A for water column profile) following Shackleton (1974). Seawater $\delta^{18}\text{O}$ was estimated
18 (Fig. 2B) from salinity using a relationship derived from local, contemporaneous salinity and
19 isotope measurements, specifically $\delta^{18}\text{O}_{\text{seawater}} = 0.6486 \cdot S - 22.536$ (see data in Meredith et al.,
20 2010). During the austral summer, at peak chlorophyll concentrations, *N. pachyderma* sin. is
21 commonly found to calcify at pycnocline depths (Mortyn & Charles, 2003; Hendry et al.,
22 2009). The predicted equilibrium $\delta^{18}\text{O}_{\text{CaCO}_3}$ values at these calcification depths are consistent
23 with the range of $\delta^{18}\text{O}_{N. pachyderma \text{ sin.}}$ values from surface sediments reported here, when a vital
24 effect correction of 0.63 ‰ is applied (Bausch et al., 1997). This vital effect correction is

1 similar to that applied to *N. pachyderma* sin. specimens collected in sediment traps during
2 2005-2006 at the nearby Rothera Oceanographic and Biological Time-Series site (Hendry et
3 al., 2009). The $\delta^{18}\text{O}$ values we measured from surface sediment samples are within the range
4 of those reported in Hendry et al. (2009; see Fig. 5P), although at the heavier end of the range
5 suggesting that *N. pachyderma* sin. is currently calcifying in warmer and/or fresher waters
6 today than the recent decades when our sediment surface specimens would represent. Surface
7 sediment $\delta^{18}\text{O}_{\text{B. aculeata}}$ values with no vital effect correction compare well with predicted
8 equilibrium $\delta^{18}\text{O}_{\text{CaCO}_3}$ values at the sea floor consistent with *Bulimia* spp. precipitating $\delta^{18}\text{O}$
9 in equilibrium with seawater (cf. Barras et al., 2010; Grossman, 1987).

10 The stable and consistently offset benthic and planktonic $\delta^{18}\text{O}$ values throughout the
11 early Holocene interval are consistent with a persistent density structure between the
12 pycnocline and sea floor, at least during the growth season of *N. pachyderma* sin., which is
13 comparable to today (Fig. 2B). This density structure would suggest that, similarly to today
14 (see Martinson et al., 2008), modified-UCDW flooded the water column to the base of the
15 pycnocline across the shelf and into Marguerite Bay. The slight decrease in benthic and
16 planktonic $\delta^{18}\text{O}$ through the early Holocene would be consistent with warming and/or
17 increased glacial melt water input. The low $\delta^{13}\text{C}_{\text{N. pachyderma sin.}}$ values (Fig. 5O) through the
18 early Holocene could result from high primary productivity and remineralisation of ^{12}C -
19 enriched organic matter below the mixed layer, diffusive mixing of ^{13}C -depleted UCDW
20 through the pycnocline (Mackensen, 2012) or *N. pachyderma* sin. inhabiting sea ice (Hendry
21 et al., 2009). Given the low abundance of sea ice diatoms, the high fluxes of *N. pachyderma*
22 sin. indicative of open water conditions and the relative warm SSTs suggested by the ratio of
23 asymm:symm *E. antarctica* we suggest that it is highly unlikely that the decreased $\delta^{13}\text{C}_{\text{N.}}$
24 *pachyderma* sin. during the early Holocene resulted from these species inhabiting sea ice. Our

1 multi-proxy dataset therefore favours an interpretation where the similar and low benthic and
2 planktonic $\delta^{13}\text{C}$ values observed in the early Holocene result from diffusive mixing of
3 nutrient-rich, ^{13}C -depleted UCDW through the pycnocline and remineralisation of relatively
4 high volumes of organic matter exported from surface waters. We acknowledge that in some
5 cases $\delta^{13}\text{C}$ from infaunal benthic foraminifera may not be entirely representative of benthic
6 water values, however we propose that the persistently low benthic $\delta^{13}\text{C}$ values recorded at
7 TPC522 throughout the early and mid Holocene are consistent with modified-UCDW
8 maintaining a constant presence at depth within inner Marguerite Bay.

9 A positive shift in planktonic $\delta^{13}\text{C}$ of 2 ‰ from at least 6992 yr BP, generating an
10 offset between benthic and planktonic $\delta^{13}\text{C}$ records of ~ 0.8 ‰, indicates ^{13}C -stratification of
11 the water column occurred at the onset of the mid Holocene interval. A 0.3 ‰ increase in the
12 benthic $\delta^{13}\text{C}$ record also occurred at the onset of the mid Holocene, although as stated above,
13 the persistently low $\delta^{13}\text{C}_{B. aculeata}$ indicate that our site was continually bathed by modified-
14 UCDW throughout the mid Holocene. We therefore consider the ^{13}C -stratification of the
15 water column to be consistent with reduced mixing of modified-UCDW through the
16 pycnocline during the winter months and significantly reduced export rates limiting
17 remineralisation of ^{12}C -enriched organic matter beneath the mixed layer and to a lesser extent
18 at the sea floor (contributing to the small amplitude change in the benthic $\delta^{13}\text{C}$ relative to the
19 planktonic $\delta^{13}\text{C}$). This proposed reduction in UCDW influence in the sub-surface waters is
20 not associated with a notable change in the planktonic $\delta^{18}\text{O}$ record, which maintains a
21 persistent offset from the benthic $\delta^{18}\text{O}$ record until 4315 yr BP. The persistent off set between
22 the benthic and planktonic $\delta^{18}\text{O}$ records suggests that seasonal stratification and the
23 preservation of a Winter Water layer, as today, was a feature common to both the early and
24 mid Holocene intervals.

1 Increased variability in both the planktonic and benthic stable isotope records from
2 4315 yr BP suggests significant shifts in sub-surface and benthic watermass properties at this
3 site during the late Holocene. Convergence of planktonic and benthic $\delta^{18}\text{O}$ and positive
4 benthic $\delta^{18}\text{O}$ excursions of up to 0.7 ‰, which may account for episodic cooling of benthic
5 waters of up to 2 °C, suggest overturning of the water column and the displacement of
6 modified-UCDW by a cold and/or more saline water mass. It should be noted that since the
7 *B. aculeata*-assemblage is episodically displaced during the late Holocene by the agglutinate
8 dominated-assemblage, considered to be associated with cold, saline waters which are
9 inhospitable to calcareous species, our benthic stable isotope record may not fully represent
10 intervals of UCDW-displacement. However, the episodic overturn in the benthic foraminifera
11 assemblage to one dominated by agglutinated species further supports the scenario for
12 UCDW being displaced by cold, saline shelf waters.

13

14 **4. DISCUSSION - MULTI-PROXY INTERPRETATION AND REGIONAL** 15 **CONTEXT**

16

17 **4. 1 Early Holocene**

18 Prior to 9707 yr BP, the retreat of the Marguerite Bay ice stream (Bentley et al., 2011;
19 Kilfeather et al., 2011) is evident in our record from the high accumulation of glacial debris
20 (Fig. 5A, 6A). Abundant Antarctic Circumpolar Current-derived *F. kerguelensis* and low
21 benthic $\delta^{13}\text{C}$ values are consistent with the continuous advection of UCDW through the
22 Marguerite Trough and over the core site through this early Holocene interval (Fig. 6B).
23 Limited sea ice and extensive glacial melt, promoted by enhanced mixing of warm, modified-
24 UCDW through the pycnocline is evidenced by mild, iron-rich and productive surface waters
25 inferred from the high ratios of asymmetrical:symmetrical morphotypes of *E. antarctica*

1 (Leventer et al., 2002), high relative abundance of *E. antarctica* (Allen et al., 2010) and high
2 *Chla* concentrations (Fig. 5C) and planktonic foraminifera fluxes (Fig. 5H) respectively.
3 These highly productive conditions are associated with depleted $\delta^{13}\text{C}$ values for *N.*
4 *pachyderma* sin. which likely result from both diffusive mixing of ^{13}C -depleted UCDW
5 through the pycnocline and remineralisation of enhanced fluxes of organic matter exported
6 from the mixed layer. At the sea floor, relatively high accumulations (Fig. 5I) of a low
7 diversity (Fig. 5J), small, thin-walled, infaunal benthic foraminifera (*F. fusiformis* and
8 *Nonionella* spp.) are consistent with intense pulses of phytodetritus (Gooday, 2003; Gooday
9 et al. 2012; Ishman and Sperling 2002). *B. aculeata*, commonly cited as an UCDW-indicator
10 species (Ishman and Domack, 1994; Ishman and Sperling 2002), dominates the benthic fauna
11 from 6992 yr BP. The low abundance of this species in the early Holocene, when all other
12 proxies point to the prevalence of modified-UCDW throughout the water column above the
13 site, may be due to out-competition by more opportunistic species or because oxygen levels
14 were too low. While *B. aculeata*, is typically associated with organic-rich sediments
15 (Gooday, 2003; Mackensen et al., 1993), and warm, moderately oxygenated bottom waters
16 (Mackensen et al., 1990; Harloff and Mackensen, 1997), the small, thin-walled species *F.*
17 *fusiformis* and *Nonionella* spp., which dominate the early Holocene interval, are able to
18 tolerate exceptionally high fluxes of phytodetritus and oxygen depleted bottom waters
19 (Gooday and Hughes, 2002; Gooday et al., 2012; Ishman and Sperling, 2002; Mackensen et
20 al., 1990). These upper and lower water column conditions persisted until 6903 yr BP.

21 Collectively, our data show that the inner Marguerite Bay deglaciation, and the warm
22 early Holocene interval that followed, were associated with modified-UCDW influence
23 throughout the entire water column at our site. This interpretation of modified-UDCW
24 influence on the inner shelf helps explain the rapid retreat of the Marguerite Bay ice stream
25 from at least 9707 yr BP, and subsequent collapse of the George VI Ice Shelf (Bentley et al.,

1 2011), the rapid thinning of terrestrial ice in inner Marguerite Bay and the onset of marine
2 sedimentation in adjacent fjords (Bentley et al., 2011; Hodgson et al., 2013). Similarly,
3 enhanced upwelling of UCDW onto the shelf prior to ~7 kyr is likely to account for elevated
4 SST (Etourneau et al., 2013; Shevenell et al., 2011) and frontal melting of glaciers (Pike et
5 al., 2013; Fig. 7E) further north at Palmer Deep and the generally warm, limited sea ice
6 conditions experienced throughout the WAP at this time (Bentley et al., 2009; Allen et al.,
7 2010).

8 **4.2 Mid Holocene**

9 From 6903 yr BP the records indicate a decreasing influence of UCDW on inner
10 Marguerite Bay surface waters, marked by extended sea ice seasons and a decline in primary
11 productivity and reduced glacial melt water-derived iron. The presence of ice during the
12 summer months, likely from glacial discharge rather than sea ice, is inferred from increased
13 abundances of *T. antarctica* (cold; Buffen et al., 2007) and low abundances of sea ice species
14 and consistent with the drop in relative SST from 5882 yr BP and reduced flux of planktonic
15 foraminifera to the sea floor. At Palmer Deep, longer sea ice seasons from ~7 kyr BP
16 (Etourneau et al., 2013) and reduced glacial discharge (Pike et al., 2013) also suggest cooling
17 occurred during the mid Holocene at the same time as the ice shelf re-formed in George VI
18 Sound (Fig. 1; Smith et al., 2007; Roberts et al., 2009). The positive shift in our $\delta^{13}\text{C}_N$
19 *pachyderma* sin. record from at least 6992 yr BP is consistent with the decrease in surface water
20 productivity and a reduction in ^{13}C -depleted UCDW mixing through the pycnocline at our
21 site. However, incursions of UCDW into Marguerite Bay continued beneath the pycnocline
22 (Fig. 6C) as indicated by the persistent influx of open ocean *F. kerguelensis* and static benthic
23 $\delta^{13}\text{C}$ values. We propose that reduced export of phytodetritus, consistent with the shorter and
24 less productive growth season inferred from the surface ocean records, allowed *B. aculeata* to
25 dominate the benthic foraminiferal assemblage from 6992 to 4153 yr BP.

1 The mid Holocene cooling trend culminates with lowest relative SSTs in our record
2 and a brief advance of sea ice at 4414 yr BP, preceding a period (4414 to 4153 yr BP) of
3 increased SST and enhanced fluxes of diatoms (Fig. 5B) and planktonic foraminifera. This
4 brief reversal of surface ocean conditions is accompanied by elevated accumulations of a
5 benthic foraminifera assemblage indicative of high phytodetrital fluxes. Warm SSTs, high
6 productivity and the benthic faunal shift indicate that nutrient rich, seasonally stratified
7 surface waters, similar to the early Holocene, were a feature of this interval. However, since
8 planktonic $\delta^{13}\text{C}$ does not decrease to early Holocene values, it would appear that mixing of
9 modified-UCDW through the pycnocline did not establish these conditions. Rather,
10 atmospheric warming in the Peninsula region (Mulvaney et al., 2012; Fig. 7D) between 5 and
11 3 kyr BP is likely to account for enhanced glacial melt along the WAP (Allen et al., 2010;
12 Pike et al., 2013) and may therefore have led to the 260 year re-establishment of early
13 Holocene-like surface conditions within Marguerite Bay from 4414 yr BP. Atmospheric
14 forcing at this time also accounts for ice shelf collapse further north (Pudsey et al., 2006) and
15 generally warm conditions along the Peninsula (Bentley et al. 2009; Allen et al., 2010)
16 centred around ~4 kyr BP (Hodgson et al., 2013).

17

18 **4.3 Late Holocene**

19 Within Marguerite Bay the transition to a colder late Holocene interval from 4153 yr BP,
20 marked by limited glacier melt water-derived iron, persistently low relative SST and
21 increased sea ice cover is consistent with minimal UCDW influence within surface waters
22 above our site. Both planktonic and benthic foraminifera became scarce, while a relatively
23 high flux of diatoms and *Chla* from 4414 to 2679 yr BP indicates high export from surface
24 waters. The fluctuating abundance of *T. antarctica* (cold) suggests variable summer sea ice
25 conditions throughout this interval and we therefore propose that the high export resulted

1 from pulses of intense productivity associated with episodic opening or retreat of sea ice
2 above our site. Episodic overturning of the water column and displacement of UCDW is
3 suggested by the convergence of planktonic and benthic $\delta^{18}\text{O}$ records and multi-decadal to
4 centennial scale oscillation between UCDW-indicator *B. aculeata* and agglutinated benthic
5 foraminifera respectively. Unlike calcareous species, agglutinated foraminifera in Antarctic
6 basins have a tolerance to low-temperature and variable-salinity conditions (Ishman &
7 Domack, 1994; Ishman & Sperling 2002). We propose that cool, dense, saline water generated
8 during sea ice formation, periodically sank to the sea floor (Fig. 6D), cooled benthic waters
9 by over 2°C (positive benthic $\delta^{18}\text{O}$ excursions of 0.7 ‰) and created unfavourable conditions
10 for calcareous benthic foraminifera species (Ishman & Domack, 1994). Benthic foraminiferal
11 (Ishman & Sperling, 2002) and $\delta^{18}\text{O}_{\text{benthic}}$ (Shevenell & Kennett 2002) records from ODP
12 1098, Palmer Deep, suggest that cyclic incursions of UCDW also penetrated the northern
13 WAP shelf from 3.7 kyr BP. The establishment of this episodic overturning of the water
14 column from 4153 yr BP at TPC522 coincides with the interval between 5 and 3.6 kyr BP
15 which appears to mark a period of transition from non-cyclic to cyclic forcing on the WAP
16 recognised in surface ocean records at Palmer Deep (Etourneau et al., 2013; Pike et al.,
17 2013).

18 From 2679 yr BP the flux of diatoms to our site decreased. The mixed calcareous and
19 agglutinated benthic foraminiferal assemblage throughout the remainder of the record is
20 consistent with continued oscillation between conditions dominated by UCDW upwelling
21 and conditions typical of saline shelf water, although, since the sediment accumulation rate
22 was significantly lower the individual oscillations are not resolved. This drop in sediment
23 accumulation rate may reflect increased frequency of oscillation between these two
24 oceanographic states. More frequent alternation between short-lived intervals of UCDW-
25 upwelling, melting back the sea ice and initiating short-lived intervals of high export flux

1 associated with and short-lived intervals of shelf water dominated conditions would have
2 allowed benthic organisms to consume and break down phytodetritus, reducing sediment
3 accumulation rates.

4

5 **4.4 CONTROLS ON UCDW-UPWELLING WITHIN MARGUERITE BAY**

6 Previous studies have failed to achieve a consensus on the influence of UCDW along the
7 WAP through the Holocene (Shevenell & Kennett, 2002; Ishman & Sperling, 2002; see
8 Bentley et al., 2009 for discussion of the conflicting ideas proposed in these papers from
9 Palmer Deep). Pike et al. (2013) also noted inconsistencies between records surface ocean
10 records from Palmer Deep. Our multi-proxy records provide compelling evidence for a
11 decreasing influence of upwelled UCDW within Marguerite Bay through the Holocene. Our
12 interpretation is consistent with a recent proxy record of glacier front melt on the WAP which
13 supports UCDW-driven glacier melt in the early Holocene, shifting towards atmospherically
14 driven-melt in the later Holocene (Pike et al., 2013). The broad correlation of atmospheric
15 temperatures in the Ross Sea region (Steig et al., 1997; Fig. 7C) and SST records within
16 Marguerite Bay suggest a similar climate forcing through the early to mid Holocene. In
17 contrast, atmospheric temperatures recorded in the ice core from James Ross Island in the
18 NW Weddell Sea do not exhibit similar trends, suggesting conditions along the WAP and the
19 Ross Sea shelf were being driven by UCDW-influences rather than atmospheric forcing.

20 Vigorous upwelling of nutrient-rich CDW during the early Holocene is also
21 evidenced south of the Polar Front by enhanced opal fluxes in the Atlantic and Pacific sectors
22 of the Southern Ocean (Anderson et al., 2009; Fig. 7G). A driver of early Holocene upwelling
23 through the Southern Ocean and WAP could be the strengthening and/or poleward shift in the
24 mean position of the SWW during the last glacial termination (Toggweiler et al., 2006).

25 Although the past position and strength of Last Glacial Maximum SWW remains elusive

1 (Kohfeld et al., 2013), the mean position of the SWW is proposed to have shifted
2 equatorward during the Holocene (Lamy et al., 2002; Lamy et al., 2010), migrating the core
3 of the Antarctic Circumpolar Current away from the Antarctic continental shelf. More
4 southerly SWW during the early Holocene would therefore have driven more frequent and/or
5 voluminous incursions of warm UCDW onto the continental shelf to mix into surface waters
6 and account for the relatively warm temperatures recorded in the Ross Sea region (Steig et
7 al., 1998) and oceanic archives along the WAP (this study; Allen et al., 2010; Shevenell et al.,
8 2011). Northwards migration of the SWW through the mid Holocene would explain a
9 significant reduction in opal flux south of the Polar Front (Anderson et al., 2009; Fig. 7F),
10 cooling in the Ross Sea region, and is consistent with a decline in UCDW-driven warmth
11 and melt water stratification in Marguerite Bay from 6992 yr BP. By the late Holocene, from
12 4153 yr BP, only episodic incursions of UCDW entered inner Marguerite Bay and cooler
13 conditions prevailed along the WAP (Allen et al., 2010).

14 A transition from non-cyclic to cyclic-forcing at Palmer Deep is recognised between 5
15 and 3.6 kyr BP (Etourneau et al., 2013; Pike et al., 2013; Shevenell & Kennett, 2002). The
16 onset of this cyclic-forcing along the WAP appears to be associated with the waning, non-
17 cyclic influence of the SWW and the increased frequency and/or magnitude of ENSO events
18 from 4.2 kyr BP (Fig. 7A; Conroy et al., 2008; Moy et al., 2002; Pike et al., 2013). From 2.5
19 kyr BP atmospheric temperatures decrease within the James Ross Island ice core record
20 (Mulvaney et al., 2013) while increasing glacial discharge to ODP Site 1098 (Pike et al.,
21 2013) suggests enhanced atmospheric warming on the WAP. Mulvaney et al (2013) propose
22 that such opposed temperature anomalies on either side of the Peninsula represents the
23 establishment of the Antarctic dipole at 2.5 kyr BP. Proxies of oceanographic conditions
24 however infer that sea surface temperatures remained low and sea ice was prevalent along the
25 WAP throughout the late Holocene (Taylor & Sjunneskog 2002; Bentley et al., 2009; Allen et

1 al., 2010; this study) indicating that oceanic forcing remained a principle driver of conditions
2 on the WAP shelf. The loss of clearly resolved UCDW-saline shelf water oscillations within
3 our benthic foraminifera assemblage record from 2679 yr BP, considered to reflect increased
4 frequency of water column overturning within Marguerite Bay, is concurrent with a
5 prominent increase in the El Junco sand record indicative of increased ENSO frequency
6 (Conroy et al., 2008). The apparent sensitivity of our record to ENSO frequency during the
7 late Holocene suggests that ENSO exerted an oceanic forcing along the WAP, as well as an
8 atmospheric forcing (Pike et al., 2013) from 4153 yr BP.

9

10 **5. CONCLUSIONS**

11 Predicted intensification of the SWW through this century (Swart and Fyfe, 2012)
12 demands better understanding of how UCDW upwelling along the WAP responded to
13 changing SWW strength and position through the Holocene. Our multi-proxy record of
14 surface and benthic water conditions provides a comprehensive history of UCDW influence
15 within Marguerite Bay, and demonstrates the apparent responsiveness of UCDW upwelling
16 to SWW through the early and mid Holocene, and to ENSO forcing during the late Holocene.

17 In recent decades a southward migration and intensification of SWW has been
18 observed (Hande et al., 2012; Swart and Fyfe, 2012). Within the same timeframe increased
19 UCDW upwelling along the WAP has increased heat flux, and likely nutrient flux, onto the
20 continental shelf (Ducklow et al., 2012; Martinson et al., 2008). Basal melting caused by
21 warm modified-UCDW approaching the Getz and Dotson ice shelves (Wåhlin et al, 2010)
22 and Pine Island and Thwaites glaciers on the Amundsen Sea shelf (Jacobs et al., 2011;
23 Walker et al., 2007), and flowing beneath the George VI ice shelf on the Bellingshausen sea
24 shelf (Jenkins and Jacobs, 2008) is the likely cause of accelerated ice sheet thinning in recent
25 years (Pritchard et al., 2012). Similarly, reduced sea ice extent and asymmetrical changes in

1 Chl *a* along the WAP since the 1980's (Montes-Hugo et al., 2009) suggest a shift towards the
2 early Holocene-like oceanographic configuration reported here. With continued strengthening
3 and poleward migration of the SWW (Swart and Fyfe, 2012), our results show we could
4 anticipate enhanced upwelling south of the Polar Front, and more frequent and persistent
5 incursions of UCDW onto the WAP continental shelf. These are changes that respectively
6 could limit the ability of the Southern Ocean to act as a CO₂ sink (Le Quere et al., 2007), and
7 threaten the stability of the extant ice shelves and feeder glaciers on the WAP.

Figure Captions

Fig. 1. Location of TPC522 (red star) and other sites (numbered in blue) discussed in this paper. 1. Taylor Dome Ice Core (Steig et al., 1997), 2. Chilean Margin (GeoB 3313_1; Lamy et al., 2002), 3. South Atlantic (TN057-13), 4. Tasmanian Gateway (E27-23; Anderson et al., 2009), 5. Adélie Land (MD03-2601; Crosta et al., 2007), 6. Lützow-Holm Bay (Igarashi et al., 2001). On the inset map red arrows indicate the flow of UCDW along the WAP with incursions onto the shelf through bathymetrical lows including Marguerite Trough. Additional sites are; 7. Rothschild Trough (Graham & Smith, 2012), 8. CTD 25; 9-10. Marguerite Bay mid-shelf (Kilfeather et al., 2011); 11. Ryder Bay, Rothera Oceanographic and Biological Time-Series site (Hendry et al., 2009), 12. Neny Fjord, (Allen et al., 2010), 13. Palmer Deep (Taylor & Sjunneskog, 2002; Ishman & Sperling, 2002; Shevenell & Kennett, 2002, Shevenell et al., 2011; Etourneau et al., 2013); 14. Maxwell Bay (Milliken et al., 2009), 15. Firth of Tay (Michalchuk et al., 2009; Mayewski & Anderson, 2009), 16. James Ross Island Ice Core (Mulvaney et al., 2012).

Fig. 2. Modern temperature and salinity profile and predicted $\delta^{18}\text{O}_{\text{CaCO}_3}$ within Marguerite Trough. (A) temperature (red) and salinity (green) from CTD25 (Number 8; Figure 1)

1 collected 2nd April 2008. Antarctic Surface Water (AASW), Winter Water (WW), modified-
2 UCDW (m-UCDW), (B). predicted $\delta^{18}\text{O}_{\text{CaCO}_3}$ calculated from temperature and salinity
3 following Shackleton (1974). Mean $\delta^{18}\text{O}_{N. pachyderma \text{ sin.}}$ (after vital effect correction of 0.63
4 ‰ from BC523 surface sediments is shown by a red data point with horizontal bars showing
5 standard deviation and vertical bars showing the corresponding calcification depth based on
6 modern predicted $\delta^{18}\text{O}_{\text{CaCO}_3}$. Average $\delta^{18}\text{O}_{B. aculeata}$ from BC523 surface sediments is shown
7 by the blue data point with horizontal bars showing standard deviation confirming that *B.*
8 *aculeata* calcifies close to equilibrium with seawater $\delta^{18}\text{O}$. Note that TPC522 is at 910 m
9 water depth.

10

11 **Fig. 3.** A. Age-depth model of TPC522. Calibrated AIOM radiocarbon dates shown in blue.
12 Green data point is the calibrated radiocarbon date derived from *Globocassidulina biora* and
13 the red data point is the omitted AIOM date. Black line is the best fit with the grey lines
14 indicating the 95% confidence interval. Sedimentation rates (cm yr^{-1}). B. Excess ^{210}Pb
15 activity in the upper 24 cm of BC523 demonstrating recent deposition of the surface
16 sediment.

17

18 **Fig. 4.** Correspondence analysis of (A) diatom and (B) benthic foraminifera assemblages
19 from PC522 showing the first three axes. Open symbols in B indicate samples where less
20 than 50 individual benthic foraminifera specimens were counted. Vertical white shading
21 bordered by grey lines indicates the standard deviation (1 s.d.) of the data on each axis. Points
22 beyond 1 s.d. are significant and were used to determine stratigraphic boundaries between
23 assemblages. Three principal assemblages were identified in each record corresponding to the
24 early Holocene (yellow), mid Holocene (green) and late Holocene (blue). The darker blue

1 interval within the late Holocene assemblage indicates an interval of high sedimentation rates
2 and improved temporal resolution where oscillatory trends can be identified.

3

4 **Fig. 5.** Multi-proxy Holocene surface and benthic records from Marguerite Bay, TPC522.

5 The upper panel shows the surface ocean records and the bottom panel shows benthic

6 foraminifera assemblages, and benthic and planktonic stable isotope records. Upper panel,

7 (A) ice rafted debris concentration (# grains $>150\mu\text{m g}^{-1}$; dark blue) and magnetic

8 susceptibility (grey), (B) total diatom flux (# $\text{cm}^{-2} \text{kyr}^{-1}$), (C) Chl *a* concentration (abs at 410

9 nm g^{-1}), (D) *Fragilariopsis curta*: *Fragilariopsis kerguelensis* ratio (E) *Thalassiosira*

10 *antarctica* (cold) %, (F) *Eucampia antarctica* %, (G) relative SST proxy *E. antarctica*

11 asymm:symm, open symbols indicate samples where less than 100 specimens were counted,

12 (H) flux of planktonic foraminifera *N. pachyderma* sin. (# $\text{cm}^{-2} \text{kyr}^{-1}$). Coloured horizontal

13 bars indicate distinct stratigraphic intervals in the diatom assemblages as shown in Fig. 4A.

14 which correspond to the early Holocene, 9707 to 6903 yr BP (yellow); mid Holocene, 6903

15 to 4213 yr BP (green); late Holocene, 4213 to 825 yr BP (blue). Lower panel, (I) Benthic

16 foraminifera accumulation rate (# $\text{cm}^{-2} \text{kyr}^{-1}$), (J) Benthic foraminifera species diversity

17 (Fischer Alpha), (K) *Fursenkoina fusiformis* %, (L) *Nonionella* spp. %, (M) agglutinated

18 species %, (N) *Bulimina aculeata* %, Open symbols indicate samples where less than 50

19 individual benthic foraminifera specimens were counted, paler coloured infill indicate

20 samples where between 50 and 100 specimens were counted, fully filled symbols indicate

21 that >100 specimens were counted. (O) benthic (*B. aculeata*; blue) and planktonic (*N.*

22 *pachyderma* sin.; red) $\delta^{13}\text{C}$. Dashed line at 0.4 ‰. $\delta^{13}\text{C} < 0.4$ ‰ indicates a diagnostic UCDW

23 signal within the water mass (Mackensen, 2012), (P) benthic (*B. aculeata*; blue) and

24 planktonic (*N. pachyderma* sin.; red) $\delta^{18}\text{O}$. Open symbols indicate samples where less than

25 10 specimens were analysed. Coloured horizontal bars indicate stratigraphic intervals distinct

1 benthic foraminifera assemblages as Fig. 4B. which correspond to the early Holocene, 9707
2 to 6992 yr BP (yellow); mid Holocene, 6992 to 4153 yr BP (green); late Holocene, 4153 to
3 825 yr BP (blue). In both panels the early Holocene, prior to 9707 kyr BP, is shown in grey.
4 The darker blue interval within the late Holocene assemblage indicates an interval of high
5 sedimentation rates and improved temporal resolution where oscillatory trends can be
6 identified until 2679 yr BP. The grey dashed lines indicate the interval of early Holocene-like
7 conditions at the transition from mid to Late Holocene.

8
9 **Fig. 6.** Schematic diagram of factors affecting surface and benthic proxy records at TPC522,
10 Marguerite Bay through the Holocene. (A) Early Holocene. Initial incursion of UCDW
11 associated with retreat of the Marguerite Bay ice stream past TPC522, (B) Early Holocene.
12 Persistent incursions of UCDW penetrate inner Marguerite Bay and mix through the
13 pycnocline, limiting sea ice and promoting glacial melt and primary productivity. High
14 phytodetritus fluxes to sea floor, (C) Mid Holocene. UCDW continues to penetrate inner
15 Marguerite Bay but does not mix through the pycnocline as vigorously as in the early
16 Holocene. Lengthening sea ice season and decreased glacial melt causes productivity to fall
17 resulting in a reduced flux of phytodetritus to the sea floor, (D) Late Holocene. Episodic
18 oscillation between UCDW incursions opening up sea ice and promoting pulses of
19 productivity and, generation of cold, dense brines as sea ice reforms which displace UCDW
20 as they sink to the seafloor. Relative size of red arrows represents the relative intensity of
21 UCDW incursions and mixing. Blue arrows indicate cold, dense saline waters produced
22 during sea ice formation. Site TPC522 indicated with yellow circle in (A). (E) Marguerite Bay
23 today (after Moffat et al., 2009). UCDW incursions into Marguerite Bay are associated with
24 reduced sea ice and enhanced glacier melt relative to the late Holocene. Given that there is no
25 evidence for major glacier readvance within Neny Fjord through the Holocene (Allen et al.,

1 2010) the glacial margin around Marguerite Bay is illustrated as being fixed through the last
2 9707 yr within these schematics.

3

4 **Fig. 7.** Holocene record of UCDW upwelling at Marguerite Bay compared with

5 (A) Relative frequency of ENSO events inferred from sand % within El Junco crater lake

6 sediments, Galapagos Islands (Conroy et al., 2008). (B), relative SST within Marguerite Bay

7 inferred from the ratio of asymmetrical:symmetrical forms of *E. Antarctica*, (C) Taylor Dome

8 δD that documents the relative atmospheric temperature in the Ross Sea Embayment (Steig

9 et al., 1998; 5 point-running average), (D) James Ross Island ice core temperature anomaly

10 that records temperatures in the NW Weddell Sea (Mulvaney et al., 2012), (E) Diatom $\delta^{18}O$

11 from ODP Site 1098 (Pike et al., 2013), (F) relative glacial meltwater flux within Marguerite

12 Bay inferred from the relative abundance of *E. antarctica* in TPC522, (G) opal fluxes south

13 of the Polar Front at TN057-13, SE Atlantic and E27-23, SW Pacific (Anderson et al., 2009).

14 Coloured horizontal bars as Fig. 5 (lower panel) with the addition of an outlined green bar

15 indicating the transition of non-cyclic to cyclic forcing observed at Palmer Deep (Pike et al.,

16 2013). Panel to the right summarises our interpretation of UCDW influence in inner

17 Marguerite Bay.
